Professor Beadle's compendious volume is the Australian contribution to the series Vegetationsmonographien der einzelnen Grossraume. After preliminary chapters on climate, soils and the flora, including its history and origins (cf. the chapter by Barlow in Flora of Australia), the various plant communities recognized are described seriatim. The communities are distinguished, named and described on the basis of the dominant species in the over-storey. This makes for numerous units ("associations" or "alliances") and for fragmentation of vegetational continua, in which the same under-storeys may continue under various canopies, and even the dominant species may almost be vicariants, replacing one another with little influence on the rest of the vegetation. Particularly is this so in the vegetation dominated by Eucalyptus spp., the description of which occupies one-quarter

The Banksias

Academic Press have recently published the first volume of a three-volume work, *The Banksias*, with paintings by Celia Rosser and text by Alex George.

The project was initiated with the aim of creating a work of both art and taxonomic scholarship. When complete, in 1988, the series will contain illustrations and detailed descriptions of all 72 species of the *Banksia* genus.

Each of the three volumes will be available only in a numbered, limited edition of 720 copies. Price of Vol.1 is £965, \$1,965. The less pecunious may arrange to see the book at the Linnean Society, Piccadilly, London, or at Academic Press offices in London, New York or Sydney

of the book, in accordance with their importance in the continent. The frequent references to ecotones underline the inadequacy of a treatment based on discrete communities defined by dominants.

The approach adopted implies that the description of a vegetation type largely consists of an account of the geographical distribution and habitat preferences of the dominant species, with a list of the species accompanying it in the under-storey. There are no association tables, and very little on the quantitative make-up of the vegetation. The treatment is mainly descriptive; vegetational dynamics are mentioned in some places, but in general the vegetation is treated as static.

The volume edited by Dr Groves is much less ambitious than that of Professor Beadle, and contains far less floristic detail. Although here, too, there is a tendency to write in terms of dominantdefined communities (as has been the tradition in Australia), some of the writers point out the drawbacks of this approach, and consider alternatives: there is in any case no attempt to treat each community separately. In consequence, the book is far more readable than Professor Beadle's. The different vegetation types are very adequately covered, but in broad groups rather than individually. Although there are inevitable differences in the treatments accorded their subject-matter by the different authors (some chapters are mainly descriptive, others have substantial quantitative components, including estimates of productivity; others again devote attention to analytical and dynamic aspects), the editor has had a good deal of success in achieving uniformity and balance.

These two books will fulfil different functions. Professor Beadle's will serve as a constant reference source on the variety, geographical distribution and floristic make-up of Australian vegetation. Dr Groves's, on the other hand, could well be used as a textbook in advanced courses, particularly where a purely descriptive approach is considered unsatisfactory.

The two volumes share some faults. Neither deals with ruderal or segetal communities, or with the sown and lightly managed grasslands which occupy such large areas in the more densely populated parts of the continent. Little attention is paid to non-vascular components of the vegetation. And, surprisingly, little notice is given to the role of domestic livestock in causing changes and determining the current pattern of Australian vegetation.

The fourth volume reviewed consists of papers presented at a symposium in Perth in 1979. The first four contributions cover plant responses to four types of stress important in Australia — lack of water; low nutrient supply; fire; and salinity. At that point, however, planning of the subject-matter becomes less noticeable, and the topics seem simply to reflect the research interests of participants. This does

not, of course, prevent individual papers being of considerable interest; one may mention, for instance, that by D.E. Gaff on "resurrection plants" — those, such as Borya nitida, which can suffer complete desiccation yet resume growth when remoistened (surprisingly, Dr Gaff does not mention lichens and arid-zone mosses, "resurrection plants" par excellence); and

that by A.J. McComb *et al.* on seagrasses. The general standard is higher than that of many symposium volumes, and the book should certainly find a deserved place in botanical libraries.

David W. Goodall is Senior Research Fellow in the CSIRO Division of Land Resources Management, Wembley, Western Australia.

Volcanology: last of the common ground

P. W. Francis

Tephra Studies. Edited by S. Self and R.S.J. Sparks. Pp.481. ISBN 90-277-1327-8. (Reidel: 1981.) DM125, \$54.50.

ICELAND is rather an appropriate venue for international meetings, and especially a NATO-sponsored one, since its position astride the mid-Atlantic ridge makes it mutually accessible for scientists from both North America and Europe. This volume is the outcome of an uncommonly successful NATO Advanced Study Institute held at Laugarvatn, Iceland, in June 1980, Several factors contributed to the success of the meeting: the participants lived and worked together in an isolated hotel, distracted solely by spectacular views of the volcano Hekla on the opposite side of Lake Laugarvatn; the exorbitant cost of liquor in Iceland ensured that most of them were able to arrive at the morning sessions fresh and attentive; and the steamy intimacy of geothermally heated sauna baths meant that ordinary barriers of communication were soon broken down. The constructive discussions that flourished in this environment are reflected in many of the contributions to the volume that resulted.

Tephra is the collective noun used to describe pyroclastic rocks. The book is something of a milestone in volcanology because it is the first to be devoted exclusively to this long neglected but increasingly important subject, which impinges on disciplines as diverse as archaeology, climatology and petrology. It is clearly a volume that libraries and tephra specialists should have on their shelves, but it may be less useful to other classes of reader, precisely because it does include such an extremely broad range of topics someone interested in marine studies, for example, would derive little benefit from sections on the use of tephra in dating archaeological sites.

Tephra studies are relatively modern. The term was first coined by the Icelandic doyen of the subject, Sigurdur Thorarinsson, to whom the book is most fittingly dedicated. Thorarinsson's introductory chapter is a model of lucid and stimulating technical writing. It is difficult to forget his account of the early Icelandic worker, who, in order to determine the limits of a tephra fall, was accustomed to pick up a pellet of sheep

droppings and take a bite at it. When he could no longer feel grains of fine ash between his teeth, he knew he was outside the zone of tephra falls. While the other 30 or so contributions do not all maintain the same high standard, and are more conventionally turgid, they are generally informative and well presented. Particularly noteworthy are the accounts by Walker of remarkably violent eruptions in New Zealand; the first serious analysis of the effects of heavy ash falls on buildings and other structures by Blong; and the startling suggestion by Steen-McIntyre that archaeological remains at a site in central Mexico, associated with tephra dated by her using the tephra hydration technique, may indicate the arrival of early man in the New World some 150,000 years before the generally accepted date.

Like many other conference proceedings, the book has been produced in camera-ready copy format. The quality of the text is perfectly adequate, but a few of the diagrams have suffered somewhat in the reproduction process from excessive reduction. A few proof-reading errors occur, but much more irritating is the editors' decision not to include the titles of papers in references. Although the space saved by their omission must be significant, so too is the inconvenience caused to readers. Other editors should be urged to reconsider their policy in this respect.

Although the book is an important contribution to the literature of volcanology, it seems unlikely that such a comprehensive study will be repeated soon! There is such a gulf between, for example, the interests and backgrounds of volcanologists studying the mechanisms of emplacement of pyroclastic flows and stratigraphers working on the use of ash layers as marker horizons in the Quaternary, that there is unlikely to be much common ground between them, and future more detailed studies will reduce this still further, until the only common factor will be the pyroclastic origin of the rocks concerned. We must welcome the publication of this book, then, as merely the first of many more specialized ones in the headlong advance of tephra studies.

Supporting international safeguards

The US State Department must now persuade Congress to back the international safeguards system — and then worry about what will happen a decade hence.

Not before time, the United States is edging in the right direction in its policy on the proliferation of nuclear weapons. Almost two years have gone since President Reagan, then merely a candidate for his office, began promising that he would repeal President Carter's Nuclear Non-Proliferation Act, passed by Congress in 1978. Now, it seems, the Administration is planning to do what it can, within the framework of the act, to remove some of the sillier restrictions on the supply of nuclear equipment from the United States made necessary by this unfortunate legislation (see page 279). But there is still no sign of when it plans to carry the fight to Congress, seeking at least to amend the Carter act. Mr James Malone's departure from the State Department (Nature, 18 March) may be a sign of impatience, but mere irritation is not a substitute for action. Part of the trouble seems to have been that the Reagan Administration, while staunchly opposed to the Carter act on the doctrinal grounds that it needlessly restricted the freedom of American suppliers to sell nuclear equipment overseas, has not fully understood why the Carter act is self-defeating. Now, to judge from the good sense of what the State Department was saying last week about the problems of nuclear proliferation, enlightenment is at hand.

How can a piece of legislation with such laudable objectives have the opposite effect, of assisting the proliferation of nuclear weapons? The explanation, now familiar, is not all that complicated. Between 1965 and 1970, the United States took the lead in persuading non-nuclear powers to sign the Non-Proliferation Treaty, then offered as the best way of controlling the spread of nuclear weapons. Persuasion was necessary because, to many non-nuclear powers, it was not self-evident that a treaty that did not restrict the right of nuclear powers to keep on making nuclear weapons could serve the stated purpose. Against the odds, however, persuasion worked. More than a hundred non-nuclear powers have ratified the treaty and have agreed to put up with repeated and unavoidably irksome visits by inspectors from the International Atomic Energy Agency.

The Nuclear Non-Proliferation Act, especially as interpreted by the Carter Administration, was a shock to this system because it signalled that in the opinion of the United States, even strict compliance with the terms of the treaty would be insufficient. The act was also a unilateral denial of the promise in the treaty that the nuclear powers would help with the free flow of nuclear technology. And by implicitly asserting that compliance with the international safeguards system would not be taken as an assurance that a signatory of the treaty was not making nuclear explosives on the sly, the act undermined the credibility of the safeguards system as a whole. No doubt the consequences would have been more serious if the civil nuclear industry had not been in such doldrums in the past few years.

The new enlightenment that has overtaken the United States Administration, well put by Mr Eugene Rostow last week, is that technical devices such as the safeguards system operated from Vienna are necessary but not sufficient means for controlling the spread of nuclear weapons. Now, as since the invention of nuclear explosives, the decisive determinants of the spread of nuclear weapons are likely to be political — that is, governments' perceptions of the international dangers that confront them and their calculations, never straightforward, of whether nuclear weapons would help or, by provoking imitation, hinder. So

governments such as that of the United States seeking to limit the spread of weapons can hope to accomplish more by diplomacy than by tinkering with the Vienna safeguards. After all, the non-nuclear powers best placed to make nuclear weapons for themselves — India, Israel, Pakıstan and South Africa, for example — are not even signatories of the treaty. In this sense, the preoccupation of the United States Congress (and of two unreflective members of the Nuclear Regulatory Commission) with the supposed loopholes in the safeguards system are strictly speaking irrelevant, and should be recognized as such. Luckily, the Administration seems to have accepted the point. Its task now is to persuade those who continue to grumble that even though it is not feasible to make the safeguards system strictly watertight, that does not imply either that the system is without value or that it should be scrapped.

No safeguards system can be perfect. The Vienna system now in force cannot, for example, guarantee that some signatory of the Non-Proliferation Treaty has not built clandestine nuclear plants in some remote part of its territory. (Surveillance satellites, however, can.) Nor can it prevent a government that has privately decided to make nuclear explosives from taking advantage of the intervals between physical inspections secretly to divert fissile materials to some hidden bomb-making plant. It is, however, unthinkable that any government would invite the trouble that would follow when it could achieve the same objectives by withdrawing from the treaty at three months' notice. Then even the best-designed monitoring instruments can break down, and the most alert inspectors be misled. The pursuit of perfection is therefore pointless. So long as the chance of the detection of violations of the rules is substantial, the international community has a reasonable assurance that signatories of the Non-Proliferation Treaty are not breaking the rules.

None of this implies that the safeguards system needs no attention. But its most serious weaknesses are not technical but administrative and financial. The new director-general of the international agency, Dr Hans Blix, has been stressing in the past few weeks that the technical qualifications of his small but rapidly growing staff of inspectors should be improved. But where will these people come from? As things are (or were at the end of 1981), 130 qualified inspectors were required to inspect a total of 850 nuclear installations, but were able to carry out only half as many inspections as they should have done. What will happen when the number of nuclear installations under safeguards has grown by an order of magnitude, and when inspections will have to be more frequent because the quantities of fissile material involved will be much larger? On the face of things, the international inspectorate will need several thousand skilled people. Is it sensible to think that they will materialize, or that their work could be organized effectively?

The danger that at some point in the future the safeguards system will collapse under its own weight is thus perhaps the most serious threat to the integrity of the whole system. What can be done to head it off? In the short term, technology has much to offer. Automatic devices for monitoring what happens in nuclear plants have been installed within the safeguards system, and will no doubt be improved (see page 279). Devices that could sample data from a distance would be potentially invaluable. There is also some reason to believe that inspection could be simplified if those

0028-0836/82/120277-02501 00 € 1982 Macmillan Journals Ltd

who operate reactors, for example, would agree that a continuous and incorruptible record should be kept of, say, neutron flux or some other physical quantity sensitive to the movement of nuclear material within them. The safeguards system now in use, devised merely to account for quantities of fissile material in the input to and the output from a reactor, does not require the collection of such data — which would in some places be regarded as an infringement of national sovereignty. It is not too soon to plan for a return of this provision at the next meeting of the signatories of the treaty three years from now.

Further ahead, there is a strong case for planning for a much more radical simplification of the safeguards system. Even as things are, governments with nuclear installations on their territory will, if they are prudent, take steps to make sure that fissile material is not spirited away. These domestic interests thus coincide with those of the international safeguards inspectorate, but the work is duplicated. The ideal, then, would be that self-policing should be done in such a way that it could be unambiguously and internationally verified. (Some concessions to this notion are already made within the Euratom system, which has its own set of safeguards.) The sooner this goal is recognized, the more likely it is to be attained. And that, in the long run, will be the best assurance that this important instrument in the non-proliferation system remains intact.

Problem not for now

Is it too soon to be worrying about who should operate the shuttle system?

If this week's space shuttle, diverted by the aftermath of heavy rain from California to New Mexico, returns successfully, the chance that it will become a white elephant will substantially have diminished. The first two flights have shown that the machine will function as intended. This time there should be information bearing on its potential usefulness. But it will be a long time before anybody will known that the shuttle will do the job for which it has been built — to put large satellites cheaply into orbit. The immediate need is to reduce the intervals between successive flights of the one machine in service — an interval artificially lengthened by the need to return it from its landing site to its launching pad in Florida but also by the need to replace whatever ceramic tiles have fallen off in flight. The plan is that the next flight but one should take off from and land in Florida, but only when there are four machines in service will it be possible to tell whether the turn-round time is really as short as planned.

So why is the United States government already in a tizzy trying to decide within what legal framework the shuttle should be operated in the closing years of this decade? It is not even as if the problem is all that novel. The development of telecommunications satellites in the 1960s is an obvious precedent. Then, as with the shuttle, there were three kinds of customers in sight — the US Department of Defense, potential users of communications satellites in the United States and customers from elsewhere, principally the international consortium of communications authorities called Intelsat. The largely successful solution was to leave the launching of military satellites to the Pentagon and to set up the corporation called Comsat as an organization independent of the government for launching and managing communications satellites.

Operating the shuttle commercially will be more complicated only in two respects. It may turn out to be uneconomic to have separate spacecraft for civil and military launchings, while, for a time at least, whoever owns the first four spacecraft will enjoy a monopoly of some kind. But there is no reason why a corporation along the lines of Comsat should not occasionally work for the military, and no reason why the temptation to make outrageous profits should not be restrained by a modicum of regulation. These difficulties will be clarified only several years from now. In the meantime, it might be thought, the US government has more urgent problems crying out for its attention.

Europe in the doldrums

Could science and technology help the EEC to a second twenty-five years?

What is to become of the European Community, which will be celebrating its twenty-fifth anniversary this week? On recent form, member governments will use what energy they can spare for the Community on now-familiar disputes about the prices that farmers should be paid for various foodstuffs or the shares to which they are entitled from this and that central fund. In their defence, governments will say that in the middle of a recession and with more than 10 million people unemployed in Europe, this cannot be the time for pausing in the pursuit of self-interest. They will also rightly say that a great deal has been accomplished in a quarter of a century. There is a customs union which works reasonably well. The Community has been enlarged (from six to ten, but Greece is shaky). And there is a sense that Europe is culturally more of a piece than it was. The snag is that the benefits are intangible, so that it is the public quarrels that stick in people's minds.

That things should have come to such a pass is easily understood. The treaty signed in Rome on 25 March 1957 was necessarily a blend of idealism and practical politics. The earlier collapse of the plan to set up a European Defence Force had warned the negotiators that even the tiniest infringement of national sovereignty would have to be made explicit and agreed in advance. Although there has recently been some talk of concerted action on defence the European Community is unlikely to be chosen as the vehicle.

The tentativeness of the past quarter of a century means that even now the Community does not enjoy economic cohesion. While private companies are required to compete with each other freely, governments can and do bias their purchases in favour of their own national suppliers, thus denying all members of the Community the benefits of scale and of an economic division of labour in some of the most important fields of technology. There was a minor sensation when British Telecom ordered new exchange equipment from a non-British corporation, but nobody appears seriously to have suggested that the British Central Electricity Generating Board should order the pressurized water reactor it wants to build from say Framatome (see page 299). Yet the European Commission in Brussels is wringing its hands over what used to be called the "technology gap" and seeking some way of strengthening the industries that its members have themselves weakened by their purchasing policies. Would it not be more productive to work out some set of inducements for persuading the member governments that they must give up their technological chauvinism?

Much the same question should soon be asked about the support of Community governments for research. Over the past quarter of a century spending by the European centre on research has if anything been set back. At the outset there was Euratom, but now there is merely the Joint European Torus and a miscellaneous programme of research at the old Euratom laboratory in Italy. Otherwise, governments deal independently with their spending on research, making separate decisions about their membership of international organizations or their spending in their domestic laboratories.

Up to a point, all this is justifiable. Governments responsible for universities also have to equip them for carrying out research, but even here there is scope for planning on a European basis complementarity between the centres of excellence that different governments support. Elsewhere, it is shocking that so little has been done to coordinate research on problems or fields of common interest. Should not, for example, something be done to concert the very considerable efforts in agricultural research, not so as to save money but in the hope of becoming more effective? The stock answer, that coordination works only inefficiently, is another way of saying that Europe is better balkanized. It would be better to devise machinery that made efficient collaboration possible.

US backs nuclear safeguards

Rostow hints at new policy on plutonium

Washington

The Reagan Administration rallied behind the International Atomic Energy Agency (IAEA) last week, claiming that a strong international safeguards system was essential for the development of nuclear commerce. It argued that weaknesses in the safeguards system should be remedied by greater support for IAEA programmes, not by changing their basic objectives.

The Administration's views were given in testimony to two subcommittees of the House of Representatives' Foreign Affairs Committee. One issue was the adequacy of the Administration's proposed contribution to IAEA in the 1983 budget. Although the increase over the 1982 contribution is larger than that for any other international organization, it will still not be enough to keep up with inflation — a source of concern to some State Department officials faced with rapidly growing demands for IAEA inspection procedures.

The hearing was also an opportunity for the State Department to rebut some recent criticisms of IAEA, in particular complaints about its admission last year (in connection with a reactor in Pakistan) that it cannot always assure member countries that nuclear materials are not diverted from peaceful to military purposes.

Such criticisms, State Department officials argued last week, are not only misdirected but also potentially harmful, tending to undermine the credibility of IAEA. Mr Richard T. Kennedy, Under-Secretary of State for Management and head of the delegation to IAEA, angrily rejected charges by Congressman Richard Ottinger that the agency had been involved in a "cover-up" by not making public its concern about the possibility of the diversion of nuclear material in countries such as Iraq and Pakistan.

Mr Kennedy was accompanied at the witness table by Ambassador Richard Kirk, deputy US representative to IAEA, and Dr Eugene Rostow, head of the Arms Control and Disarmament Agency. Each spoke strongly on the theme that the agency requires as much support as possible from the industrialized nations, and that the adequacy of safeguards should not be considered in isolation, but merely as one element in the control of nuclear proliferation.

Thus Mr Rostow told the subcommittees that halting the spread of nuclear explosives was "inconceivable" without IAEA safeguards, but added that they did not prevent diversion since, for example,

they did not permit searches for clandestine materials or facilities. "In my view, it is just as wrong to overestimate the importance of safeguards in nuclear commerce as it is to denigrate the system for not accomplishing objectives for which it was not designed," Mr Rostow said.

The State Department's consensus on IAEA, however, was not shared by all members of the Nuclear Regulatory Commission (NRC). Under the terms of the Nuclear Non-Proliferation Act of 1978, the commission is responsible for checking that safeguards are applied to any foreign nuclear installation to which nuclear materials are being exported from the United States.

Mr Peter Bradford, on his last day as one of the five members of NRC, was outspoken about the difficulties experienced by both NRC and congressional committees in obtaining data by which to assess the effectiveness of the safeguards. At one point, he accused the State Department of unnecessarily censoring NRC's reply to questions submitted by Congressman Richard Ottinger.

Mr Kennedy refuted the charge of censorship, pointing out that the information was being withheld at the request of the Central Intelligence Agency—which has since offered to brief Mr Ottinger on the subjects that he had inquired about. Both he and Dr Rostow, however, declined to say whether the State Department has evidence of the diversion of nuclear materials.

Both Mr Bradford and a second NRC

commissioner, Mr Victor Gilinsky, expressed reservations about the adequacy of IAEA inspection procedures for warning about the diversion of weaponsgrade plutonium from reprocessing or enrichment facilities — concerns which led the Carter Administration to attempt to dissuade other countries from adopting such technologies.

Dr Rostow in reply criticized the previous Administration's approach, suggesting that attempts to impose unilateral controls could backfire by encouraging the spread of reprocessing while making less likely the agreements on a common policy with other nuclear suppliers. The Administration's policy is soon to be defined in a new executive order which Mr Reagan is to sign; Dr Rostow said it was important to acknowledge that civil reprocessing in the stable industrial democracies did not in themselves present a proliferation risk.

On the IAEA safeguards, Dr Rostow urged that member states should provide the international safeguards system with the resources needed. Mr Kirk, however, told the subcommittees that as the number of installations under IAEA safeguards had risen from 560 in 1977 to 850 in 1981, even though the IAEA budget allowed much faster growth for safeguards than in other activities, its expansion of the safeguards system had caused "a resources pinch, growing pains in IAEA's administrative structure, and a lag in IAEA safeguards coverage".

David Dickson

Nuclear monitoring by telephone

Washington

A scheme for collecting nuclear safeguards information by means of telephone lines is to be discussed at a meeting planned for Vienna in June this year. The system, called the Remote Continual Verification programme (or "RECOVER"), which was given a systematic trial in the autumn of 1980, has grown out of the technical proposals for the remote verification of arms control agreements in the draft of the Comprehensive Test Ban Agreement, uncompleted since the end of 1980.

In evidence to the House of Representatives last week, Dr Eugene Rostow said that on the basis of a cost-benefit study carried out at Brookhaven National Laboratory, the Administration was now hoping that the system could be put into service soon, and that it might even be valuable in the verification of treaties (yet to be negotiated) on chemical and biological weapons.

In the nuclear context, the new system is a means of making sure that automatic monitoring equipment does not break down between visits by inspectors from the International Atomic Energy Agency (IAEA). This is done by the repeated but irregular interrogation of monitoring equipment by means of signals transmitted on the international trunk telephone system. So that the authorities responsible for safeguarded nuclear installations cannot corrupt the signals received and sent, signals are encoded by means of an unbreakable code of the type developed for use in what is now called public-key crytography.

The Brookhaven study has apparently shown that the new monitoring system is potentially most valuable in nuclear installations such as reactors which can be refuelled on load and in fast critical assemblies, to which frequent visits from inspectors are at present required. One critical assembly in Japan, containing a fixed quantity of 300 kg of plutonium and 200 kg of enriched uranium, has on present criteria to be inspected every week or two.

The new monitoring system, by reducing the frequency of inspections, would save an estimated \$200,000 a year at that installation alone. The system is, however, unlikely to be used at separation plants (where inspectors are virtually permanently in residence) or in light-water reactors (where redundant monitoring equipment is probably cheaper).

In Japan, the system is also being advocated as a means of safeguarding the sea transport of fissile material, providing a means of making sure that cargoes are not illicitly diverted on the high seas. In such an application, communication would be by means of Earth satellites of the kinds being developed for marine navigation. The effective use of the system for the inspection of nuclear installations on land is thought to require the development of a network of IAEA field stations (of which there are at present only two, in Toronto and Tokyo) and the existence of an efficient trunk telephone system (found wanting in Bulgaria during the 1980 trial of the system).

The application of the system to the monitoring of agreements on chemical and biological weapons presupposes the design and installation of effective automatic monitoring equipment at plants covered by an agreement.

Soviet nuclear power

Signs of caution

The Soviet nuclear energy programme is running into difficulties. In spite of the high priority given to power station construction, last year's targets were not met. And although no specific reference has been made to the need for greater standards of safety, Pavel Falaleev, first deputy Minister of Energy and Electrification, has said that the safety requirements of power stations were being tightened despite the radiation around them being "considerably below the permissible limit and practically no different from natural levels ". In a Soviet context such a remark is sufficient to indicate considerable high-level rethinking.

The discussion of the nuclear programme began about six weeks ago, with a meeting of the Central Committee of the Communist Party to review shortcomings, where the emphasis was on the logistics of construction although inadequacies in the design sector were noted.

Three weeks later, the theme was taken up in a leading article in *Pravda*. This at first followed the line of the central committee meeting, noting that production-line nuclear power units had already been developed, and that supply problems could be dealt with by economic sanctions to penalize those who held up the plan. *Pravda* then went on, however, to suggest serious deficiencies in the design sector.

Here, it was claimed, the Ministry of Energy and Electrification had failed to exercise its supervisory duties. Changes in materials and specifications had been made without either proper justification or the

Sticky problem over Iraq fuel supplies

Two French nuclear physicists, backed by three prestigious members of the Académie des Sciences, have warned President Mitterrand in a report that there would be no easy way to stop Iraq making bomb-grade plutonium—if France rebuilt the Osirak reactor destroyed in a bombing raid by Israel nearly a year ago.

This is the second report condemning the reactor sale to be prepared by the two physicists and to be sent — unsolicited — to the president who is said to be sympathetic to the arguments but to be short of apolitical technical advice.

What stung the physicists to produce a second report were widely-reported claims that "caramel"—a low (7 per cent) enriched uranium oxide fuel—was the answer to the problem. If caramel were sold to Iraq to fuel the reactor, in place of the 95 per cent enriched uranium for which it was originally designed, the claims went, Iraq would have no quick route to the atomic bomb.

However, this misses the point, the new report stresses. The caramel fuel would still produce the same neutron intensity in the large pool around the reactor, where test materials are placed to investigate their reaction to neutron bombardment. If these test materials were replaced by depleted — or natural — uranium (of which Iraq is believed to have supplies) plutonium would be produced in the uranium, and could be extracted chemically.

The only advantage of caramel is that it cannot be used directly to make bombs, whereas 95 per cent enriched uranium is more easily converted. But, the reports point out, four years ago Giscard d'Estaing set limits on deliveries of enriched fuel to Iraq. Fuel would be sent in single reactor-loads of 13 kg, each of which would be loaded into the reactor under supervision and promptly irradiated making diversion technically very awkward. From that time, the diversion of the fuel itself ceased to be a problem — so the use of caramel solved nothing.

The production of plutonium by neutron bombardment, however, could amount to 3.3-8 kilogramme per year (to quote the assessments fo both the Commissariat à l'Energie Atomique and the International Atomic Energy Agency). The amount of plutonium required for a bomb is generally taken to be 6 kg, although under certain circumstances 1-2 kg could be enough. Thus, say the two reports. Iraq could have the capability (in plutonium, at least) of producing a bomb within six months of beginning irradiation, whatever fuel the reactor was loaded with. IAEA inspection, however, might interfere considerably with this rate of production.

France has said it will help rebuild Osirak, provided Iraq guarantees that the reactor will be used entirely for peaceful purposes. The new report may make this politically more difficult for the president.

Robert Walgate

apparatus for selecting the "most progressive" solution to engineering problems. In particular, a proposal put forward by the *Atomenergostroiproekt* design trust, for a change in the structure of the "protective shells" of power stations, was turned down without being studied by the necessary multi-disciplinary panel of experts. The scientific council of the ministry, *Pravda* said, must bear greater responsibility for such decisions.

This reference to protective shells is significant. If, as seems likely, this refers to the concrete containment vessel common in Western power stations, it reflects a change in Soviet policy. Until recently, such vessels were dismissed by Soviet designers as unnecessary, and a capitalist ploy to raise construction costs. Demands from the Finns and Hungarians led them to introduce containment vessels into reactors designed for export. The remark in Pravda suggests that they may now have been introduced into reactors for home use whereas previously it was thought sufficient to surround reactors on the outskirts of major cities with a kilometre or two of parkland or playing fields.

Vera Rich

Intelligence testing

Soviet inequality

The Russians have finally "come out" on the subject of intelligence and other objective tests of performance and personality. The January/February issue of Voprosy Psikhologu (Problems of Psychology) contains three papers endorsing such tests in principle.

The papers are printed prominently at the front of the journal, preceded only by a major statement on future psychology services policy, based on the decisions of the November plenum of the Soviet Union's ruling communist party. The journal quotes President Brezhnev himself in support of a call to concentrate on "scientifically-based solutions to the problems of the nation's education in the service of the scientific and technological revolution".

This is a startling but unequivocal volteface by the Soviet authorities, who have until now (in public at least) regarded "testology" as an instrument of class warfare in the hands of the ruling capitalist élite. Testing was even made illegal in Russia in 1936 by an edict that may now have to be hastily repealed.

One of the most extraordinary admissions in the first paper, by K.M. Gurevich, is that there are still significant class divisions inside Soviet society, as well as national cultural differences within the empire, which test content must take into account.

Western workers in the field of intelligence testing may also prick up their ears at the news that foreign tests are already in use (presumably in the enforced absence of nationally-devised and standardized ones). In fact, it was the use of such tests which originally brought testing into disrepute in the Soviet Union. Gurevich advises: "Above all, when embarking on a study with one of these (foreign) tests, it is vital to decide what contingencies it makes sense to employ in order to make it an appropriate instrument for carrying out an investigation under conditions very different from those under which it was created". A citation at the end of his paper shows that Gurevich recently published a book on the subject (Psychological Diagnostics, Problems and Research, Moscow, 1981).

In the second paper, V.I. Slobodchikov makes an interesting distinction between "suitable" uses of test procedures — that is, they may be used for discrimination and selection but not for "controlling development or in remedial education".

At the opening of the third paper, by Yu. Z. Gil'buch, the British intelligence tester Professor H.J. Eysenck is accused of epitomizing the "mechanistic" attitude to testing. This does not deter Gil'buch, head of a Kiev laboratory, with more than twelve

years of published work on the subject, from concluding his piece thus:

"The fundamental question at the root of any discussion about content validity in intelligence tests is this: what underlies individual differences in the degree of mastery of mental operations as exemplified in any particular culture (as represented in tests)? Is it mostly factors of biological inheritance, innate gifts, or is it (alongside and in interaction with these) the conditions of education and upbringing, which in various families and various schools are unavoidably present in greater or lesser variety?."

Soviet test experts are frantically trying to

devise tests which allow for different norms within classes and national cultures, but which will also serve the practical purpose for which the tests have been revived — namely, the more efficient selection of personnel to man their scientific and technical revolution.

The present aim of Soviet psychologists seems to be to devise tests which tap the purest, least culture-bound workings of the brain, such as solving abstract puzzles, chess problems and devising imaginary games.

Just how important this is to the Soviet Union is summed up by Gurevich thus: "In our country at present the growth of psychological diagnosis has become one of the most vital supports of theoretical and applied studies in the field of education, farming and management. In pre-school education, high school and professional training, methods of psychological diagnosis must be used to assess levels of psychological development: this allows for the inevitability of change within the very process of education, and provides a broad base from which it can advance to rationalization and improvement."

Elizabeth Roberts

Biological warfare

Soviet use

Washington

The Reagan Administration claims that it now has clear and scientifically verified data that the Soviet Union is providing toxic agents for military use by its allies in Laos and Kampuchea, and has circumstantial evidence that the Soviet Union is itself using such weapons in Afghanistan.

The evidence is contained in a report presented to Congress by Secretary of State Alexander Haig last Monday, providing a detailed analysis of eyewitness reports, chemical analysis of samples and information from other sources gathered over the past seven years.

According to Under-Secretary of State Walter Stoessel, the evidence shows that the Soviet Union has been engaged with its allies in the use of weapons that are forbidden by the Biological and Toxin Weapons Convention of 1972. "The USSR is flagrantly and repeatedly violating international agreements, and this is now a threat to the whole international community, since toxin weapons are a cheap, convenient way of subduing and exterminating opposition which could be used against other people", Mr Stoessel said.

The State Department's report is intended to stem sustained criticism that it has failed to substantiate its allegations of the use of chemical and toxin weapons — and in particular of tricothecenes — with adequate medical and scientific data.

Various other hypotheses have been put forward to explain the presence of tricothecenes in samples which have been brought back from South-East Asia and

Incriminating data

Washington

The State Department report details how the evidence for the occurrence of mycotoxins has been obtained. It says that the US Army's Chemical Systems Laboratory was unable to detect them in the few samples returned from South-East Asia, so that Dr Chester J. Mirocha from the University of Minnesota was asked to apply his gel-separation and mass spectrometric techniques to the problem.

Three closely related mycotoxins are said to have been identified: T-2, nivalenol and deoxynivalenol. A sample of material thought to be contaminated and obtained from Kampuchea contained 109 p.p.m. of nivalenol, 59.1 p.p.m. of deoxynivalenol and 3.15 p.p.m. of T-2. Control samples of vegetation, submitted for analysis gave negative results.

Samples of water from Laos and Kampuchea contained 150 p.p.m. of and 25 p.p.m. diacetoxyscirpenol, another closely related toxin. A sample of yellow powder collected after a supposed attack by chemical weapons showed no evidence of toxins but did yield a yellow pigment, similar to one found by Dr Mirocha in a culture of Fusarium roseum. The report says that this may mean that the agents used in South-East Asia are crude extracts of Fusarium cultures.

A crucial element in the State Department's case is that the concentrations found in the samples from South-East Asia are greater than those associated with natural contamination. Typically, the latter yield only a few parts per million of mycotoxin, although one measurement of 41 p.p.m. of mycotoxin in contaminated grain in the United States is on record.

The report includes names of Soviet scientists and of four laboratories thought to be involved in research with mycotoxins. The laboratories are the Institute of Experimental Veterinary Science (Moscow), the Institute of Microbiology and Virology (Kiev), the Institute of Nutrition (Moscow) and the Institute of Epidemiology and Microbiology (Moscow). There is no suggestion that the research there is military in character.

analysed in US laboratories. Some have claimed, for example, that they could have come from various forms of rat poison, others that they might be the residue of naturally occurring fungus.

State Department officials, however, said at a press conference on Monday that they had looked closely at the various alternative explanations and had not been able to substantiate any.

Mr Richard Burt, the department's

director of political and military affairs, pointed to extracts from an East German military manual printed in the report which gives details of how toxin weapons might be used, pointing out that the suggested circumstances were similar to those reported in South-East Asia.

"We think Laos, Cambodia (Kampuchea) and Afghanistan are 'proving grounds' for testing the chemical and biological weapons capability of the Soviet Army", Mr Burt said. "In all three countries there is strong local resistance which stands in the way of Soviet objectives, and where the conventional use of troops would be very costly."

Department officials refused, on national security grounds, to say how all the various samples and reports had been obtained. In analysing the samples, Mr Burt said, the department had received technical cooperation from the British government as well as the Japanese.

Disputing press reports that tricothecenes were not powerful enough to be a useful tactical weapon, Dr Sharon Watson of the Army Surgeon General's Office said that experiments carried out at the army's testing centre in Fort Detrick, Maryland, had shown that haemorrhaging, caused by a severe impairment of blood-clotting, could occur at very low exposure levels. Experiments had shown that for a 70 kilogramme man the LD50 dose could be as low as 35 milligrammes.

Furthermore, Dr Watson said, the army had reason to believe that a crude extract from *Fusarium* was being used, which could be more toxic than the purified form. Referring to the broader implications of the charges being made against the Soviet Union, Mr Burt said that the evidence for the use of toxins in South-East Asia illustrated that one of the major flaws in the 1972 convention banning the use of toxins in war was that it contained no provision for verifying compliance.

Information technology

Cables coming

If Britain does not prepare to accept cable information systems now, then it may as well not bother at all. That is the message contained in a report to the Cabinet Office which was prepared by the government's Information Technology Advisory Panel and published earlier this week. Such is the urgency perceived by the panel of the need to provide cable television for British viewers that the report urges the government to make its intentions clear even before fully resolving some thorny problems such as regulation and licensing of the programmes that can be transmitted.

The government seems set to take on board the gist of the report's recommendations which include announcements of broad policy by mid-1982, regulatory arrangements by early 1983 and the

formulation of technical standards for the cable network by the end of this year. Civil servants in several government departments are now trying to work out the details. Thus the more leisurely approach to cable television which was envisaged as recently as early last year, when the Home Secretary approved 13 pilot schemes, looks like being abandoned. Decisions must now be taken, according to the report, before the results of those schemes can be known, in order to prevent overseas companies from hastening the decline of the British cable television industry.

The chief interest in cable systems is said to lie in their potential for linking new information technologies. But the panel believes that large numbers of users will only be attracted to the system quickly if it starts by offering a wide choice of television programmes. Mr Charles Read, chairman of the panel, hopes that programme providers can be licensed within existing legislation, which gives the Home Secretary wide powers of discretion.

Public fears about the quality of broadcast programmes, which traditionally have been tightly controlled in Britain, may not be so easily allayed. This problem will soon be tackled by Lord Hunt, formerly secretary to the Cabinet, who is to hold an urgent inquiry into the likely effects of cable television on the public broadcasting system.

Precise specifications for the cable system have yet to be established. But the panel's report envisages series of local networks, initially in large cities, that would offer broad bandwidth communications capable of carrying 15-24 channels. British packet-switching technology that would allow cable to individual homes to be of lower bandwidth than that on trunk lines is favoured.

The cost of cabling half the British population, according to the report, would be about £2,500 million, all of which would have to be found by the private sector, which apparently is eager to put up the money.

Costs, says the report, might be minimized if British Telecom ducts were used for laying the new cable. Local networks could, for example, be interconnected via its own telephone network. And as private broad bandwidth cables may well be installed before its own network is upgraded, the company would be wise to consider putting some of its own services, such as Prestel, onto the new cables.

While welcoming British Telecom's interest in the new cables systems, the panel's report is nevertheless cautious about the extent of the company's involvement. It is particularly keen, for example, that British Telecom should not dictate the standards for the new networks, presumably fearing that the company would be too restrictive and cause unnecessary delay.

Judy Redfearn

Neuroscience moves

New York

The Neurosciences Research Program, the seemingly clubby survival from the time when it seemed necessary, twenty years ago, to persuade people that neurobiology was interesting, is in the throes of moving from Boston to New York. At the same time, it has been given a new image and an income that it can call its own.

The organization was begun in 1962 by Professor Francis O. Schmitt, largely to proselytize on behalf of the neurosciences. Since then it has been housed in a replica of a French chateau 15 miles from Boston, and has been best known for its periodic small workshops (up to six a year) on various aspects of neurobiology. Now, however, the organization has negotiated a lease with Rockefeller University that will allow it to house not merely its administrative staff but a new institute, called the Neurosciences Institute, intended to provide up to half a dozen relatively senior people in the field (and perhaps as many junior colleagues) with an opportunity for conceptual (as distinct from experimental) work for short periods of time.

Both parties to the lease now signed are anxious to emphasize that the Neurosciences Research Foundation, by becoming a tenant of the university, will not become a part of it. The foundation will in future finance both the Neurosciences Institute and the Neurosciences Research Program from an income that appears to exceed \$500,000 a year.

In the move from Boston to New York, some care seems to have been taken to broaden representation in the management of the enterprise, with the result that it is often hard to tell who will do what. The director of the Neurosciences Research Program from the president of the foundation) is Dr Vernon B. Mountcastle, President of Johns Hopkins University. Dr W. Maxwell Cowan of the Salk Institute is the chairman of the Scientific Advisory Committee of the programme, but there is also a "scientific" chairman, Dr Gerald M. Edelman of Rockefeller University (who is also the director of the Neurosciences Institute).

Representation of the Salk Institute through Dr Cowan, is said to mark the plan that both the Neurosciences Research Program and the institute will be peripatetic, migrating en masse to the west coast for the summer months. Edelman hopes that the first of these summer programmes will take place this year, although formal arrangements with the Salk Institute have not yet been completed.

Polish crisis

Patriotic science

The role of science in overcoming Poland's economic difficulties will be a major point on the agenda of the next plenum of the Central Committee of the Polish United Workers' Party, Dr Hieronim Kubiak announced last week. Dr Kubiak, reputedly one of the most liberal members of the politburo, was addressing a national conference on "the role and tasks of science in getting the country out of the economic crisis".

Dr Kubiak stressed that "although science has no country, scientists do have countries", and appealed to the patriotic sentiments of all Polish scientists, asking them to rally to the new economic strategies.

From the Academy of Sciences, Dr Zdzislaw Kaczmarek, the scientific secretary, who holds quasi-ministerial rank and is accountable directly to the prime minister, announced a new government act, which will define the legal obligations implicit in scientific consultancy. Not every researcher, he said, has the qualities needed by a consultant, such as the ability to translate the language of science into the language of politics, and, most important of all, the courage to oppose "irrelevant" pressures.

The timing of the meeting was not without irony. On the same day, the Central Committee Commission for Health and Environment discussed a report on the disastrous level of environmental pollution - a subject which, until September 1980 could only be discussed in clandestine unofficial pamphlets. Even during the 16 months of Solidarity, the most revealing data, including the fluorine pollution of the Krakow area, could only be discussed in "internal" bulletins of the Polish Ecological Club. Yet now the commission cited "lack of adequate education" and information as a major cause of the current pollution levels. A few days before these meetings, another report had been under discussion in the Polish media discussion of the factors leading up to the imposition of martial law, produced by the "Experience and Future" group (Doswiadczenie i Przyslosc, or DiP), an unofficial working party of intellectuals set up in 1978 to discuss the state of the country. In spite of official disapproval, DiP produced several reports on the economic crisis and proposed strategies for overcoming it. The latest such report, drawn up on 20 December, was ignored by the authorities until early March, when it was officially condemned as a Western forgery - although the same commentators then proceeded to vilify Stefan Bratkowski, head of DiP and chairman of the now-suspended Union of Polish Journalists. At least 30 scientists actively participated in DiP and have thus,

effectively, had their proposals for the economy already rejected. How far they are liable to respond to Kubiak's patriotic appeals is unknown.

One notable figure, however, was absent from the meeting with Kubiak - Dr Aleksander Gieysztor, president of the Polish Academy of Sciences. He had been allowed to travel to Paris, to be honoured by a learned society for his contributions to historical research. The Paris ceremony was kept deliberately low-key, since Dr Gieysztor had made it clear that he was present solely in his private capacity, and not as a representative of the Polish Vera Rich scientific establishments.

Universities in commerce

Stanford's way

Graduate students at Stanford University, denied entry to this week's conference on academic-industrial relations organized by the university's president, Dr Donald T. Kennedy, are holding a rival conference of their own in public. The Stanford graduate students' association has organized one meeting for 26 April and another for 10 May. The students' objectives are to help define their own reactions to the involvement of outside commercial interests in academic research and towards academic supervisors who acquire equity and managerial positions with companies whose interests are related to their research.

Kennedy has agreed to be the keynote speaker at the first of the students' meetings. Professor David Noble of the Massachusetts Institute of Science and Technology and author of American by Design, a study of the links between science and technology and the growth of corporations, will also be speaking.

For Kennedy's own meeting this week the presidents of Harvard University, the California Institute of Technology, MIT, the University of California and Stanford, together with teams of academic colleagues and industrial partners, are turning up at Pajaro Dunes. A possible code of practice to regulate the relationships between universities and commercial interests has been circulated, but even if this or some amended code is agreed on, the result will still have to be discussed within the faculties of the five universities.

One of Kennedy's messages for the students is likely to be that industrial corporations can contribute both financially and technically to the education of graduate students. He will be able to point to the arrangement now concluded between Stanford's new Center for Information Systems and seventeen major electronics companies, which will contribute \$250,000 a year for each of the next three years towards the general running

Meanwhile, Stanford is taking steps to

Joint Research Centre

Jean-Albert Dinkespiler, an old hand at European research efforts, is to take over from Professor Stelio Villani as Director-General of the European Community's four "Joint Research Centres". The four centres at Ispra (Italy), Geel (Belgium), Karlsruhe (West Germany) and Petten (Netherlands) employ about 2,000 European scientists, and boast a budget for the period 1980-83 of 510 million European Currency Units (£287 million).

Dinkespiler, a 55-year-old Frenchman, has already seen active service at the French national centre for space studies, at the European Space Agency, as Deputy director-general of the Joint Research Centres and head of Ispra and most recently as director-general responsible for science, technology and energy at the Council of Ministers.

Jasper Becker

regularize the distribution and use of what is called "tangible research property" unpatentable products of research which may, nevertheless, have commercial value. New guidelines for the distribution and use by others than the original scientist have been drawn up partly to draw the attention of investigators to the possible commercial importance of such things as cell lines, computer data bases and software. circuit diagrams and engineering drawings.

Dr Gerald J. Lieberman, vice-provost at Stanford, says that investigators who create tangible research property should ordinarily be the ones who decide how it should be distributed or used. Such property should not be sold for profit, but steps should be taken to see that the assistance provided by academics at Stanford is afterwards recognizable (and, if necessary, acknowledged in writing). The objective seems to be to encourage researchers to assist their colleagues elsewhere while not hazarding the university's right to control the exploitation of those developments which turn out to have commercial value.

Charlotte Beyers

CORRESPONDENCE

Creation deduced

SIR — Having recently received, for the first time, a communication from the Biblical Creation Society which contained quotations both from my letter to you of last July (*Nature* 30 July 1981, p.403) and from Dr O'Grady's comments on it (*Nature* 10 December 1981, p 510), I am reminded that a short rejoinder to the latter is needed.

It was kind of O'Grady to think that I needed information about the writings of Messrs Hume and Popper on deductive and inductive thinking. However, what I was trying to do - perhaps not clearly enough was to put into perspective the original dichotomy between the two modes of explaining things, a division which must surely go back, as I said, to the earliest days of man as a toolmaker. In those times deduction must have more or less automatically meant a preconceived belief in, and an assertion of the truth of, dogmas and myths. Only, I suggest, with the emergence of properly understood scientific reasoning within the past few centuries, involving the testing of ideas, has deduction acquired its constructive aspect and become an alternative to induction in the formulation of hypotheses which make testable predictions.

My main point was that the original "prehistoric" form of deductive thinking is still with us and flourishing - perpetuating many myths both ancient and modern. I believe "creation science" is a classic example of this as it seems only concerned to propagate, in the face of a mountain of contrary evidence, a 3,000 year old myth about the origin of the Earth and of man. If this is not so, and if creationism is scientific. deductive thinking, someone will have set out the creationist hypothesis in much more detail than appears in Genesis and will have tested it sufficiently often and successfully to think it worth continuing. Has this happened? Perhaps the three Glasgow University biochemists (see Nature 26 November 1981, p.302) have done this as well as simply stating, rather negatively, that the evidence does not disprove the existence of a Creator?

EUAN W MACKIE

Hunterian Museum, Glasgow, UK

Kindly explained

Sir - Marks1 as well as his creationist critics²⁻⁵ seem to be arguing at cross purposes. Unlike Marks, one ought not to sneer at the views of fundamentalists, just as a clinician must not disregard the delusions of a psychotic. Both types of belief mean much to those who hold them A creationist cannot be convinced by facts or scientific arguments of any possible errors of an a priori infallible creed, any more than a psychotic can be shaken about the absolute truth of his delusions by rational counter-arguments. When contrasting science and creationism we must remember that we are dealing with different kinds of explanations concerning the world. Let me paraphrase in an evolutionary context a passage from the late C.A. Mace written in a behaviour-scientific context in an editorial foreword to a book by Vernon⁶.

"The difference between evolutionists on the one hand and creationists on the other arises perhaps from a failure of the latter to do justice to the fact that there are many different kinds of explanations. There is the kind of explanation that fossils exist, which simply says that fossils are remains of past organisms, irrespective of whether these organisms were divinely created or arose by self-organization. This is a neural kind of explanation. There is the sort of explanation which appears to satisfy evolutionists and some other life scientists, which takes the form of saying that fossils are relevant to our formulations of particular theories of evolution-specific mechanisms7. There is another kind of explanation which satisfies materialisticallyminded mechanists, who (like myself⁶) suggest that fossils are the remains of organisms that arose by self-organization. Perhaps also some notice should be taken of the kind of explanation which satisfied children and devout old ladies who would say that fossils exist because God arranged things so as to remind us of the many beautifully adapted organisms that he has created in the past.' There is room for all of these views among the right people in the right places and in mutually exclusive ways. We must remember that different kinds of explanations rely on different premises and on different explanatory procedures. Thus, hypotheticodeductive scientific theories are not intended to proclaim absolute truths, but are, or should be, falsifiable. By contrast, the doctrines of creationists are proclaimed as absolute truths of a metaphysical kind, and do not function like scientific hypotheses. If scientific facts do not fit creationist doctrine then, with sufficient ingenuity, an indefinite number of reinterpretations of the doctrinal metaphysical statements remain possible. In the Popperian sense there exists an unlimited range of built-in metaphysical defences of fundamentalist doctrines. It is therefore not uncommon for scientists to accept two schemes which may be related to the same facts. On the one hand they may accept hypothetico-deductive theories of mechanisms. On the other hand they may embrace a metaphysical belief system which explains some of the facts known to them from science in ways totally different from the ways in which they occur within scientific theories. I know many such people and some highly intelligent ones among them, although I see no personal need to supplement science with a fundamentalist metaphysics. (Some kind of metaphysics is probably needed

Aptly put

Sir — The comparison of spontaneous development of life to the creation of a Boeing 747 by a "tornado sweeping through a junkyard", cited by Jukes (see Nature 18 February, p.548) as being inept, is, on the contrary, very apt. Probably purposely, but possibly inadvertently, Jukes fails to identify the Wright brothers, Dumont and Blériot as creators. Every additional step in the development of the 747 is a result of creative minds. Without such creative genius, and with or without any number of tornadoes, a junkyard is still junk, albeit with useful materials for creative minds; and without a Creator, atoms and molecules, which He created, are still only atoms and molecules. (Go back farther to matter and energy, if you wish.) In referring to the creators of the modern aircraft (those he mentions and their successors), Jukes has most elegantly refuted his own argument.

The real dangers

SIR — With regard to the correspondence from Chris Q. Doe (Nature 4 March, p.8), I think it is Mr Doe who is demonstrating "extreme ignorance". The statement that "any amount of radiation will produce a proportional increase in mutation rate" is an unproven supposition, and a highly doubtful one in view of recent results on the self-repairing abilities of DNA (of which Mr Doe should be aware if he is really a biologist)

As for the relative dangers of hydroelectric versus nuclear power plants, it is a fact that several thousands of people have been killed by collapsing dams during the past twenty years alone, while the number of fatal casualties caused by nuclear power plants can be counted on the fingers, not a single one occurring to people outside the plants (except possibly in accidents due to construction work traffic). The increased mutation rate caused by nuclear plants is, again, highly hypothetical; even if it exists, it cannot amount to more than a fraction of a per cent of the rate caused by natural radiation, itself a small fraction of the rate of mutations occurring spontaneously or caused by chemical agents. Who says that mutations are necessarily harmful, anyway? Darwin would have thought well of them had he known about them

What science has to do with the soundness of decisions to build nuclear power plants is beyond me; as for the economics of it I leave that to the electric utilities, who presumably aren't building them just for the fun of it. Living in a country which is seeing its forests and lakes rapidly being destroyed by acid rain (already the fish are gone from 10,000 lakes in Sweden, many are practically devoid of life), I have no doubt at all, however, that nuclear power is the environmentally soundest way of producing the energy we cannot do without, and by far the one doing the least harm to nature, both momentary and permanent, and with all aspects considered.

Vasterås, Sweden

SCIENCE IN FRANCE

The grand experiment

SCIENCE in France is going for boom — or bust. The objective is to be the (socialist) Japan of Europe, and new technologies, founded on good science, will lead the way. What a contrast with the rest of the developed world. It is a great experiment, which deserves to succeed. Of course, along the way there will be many pitfalls, and in the next few pages an attempt is made to reach an objective assessment of the situation.

In fact, the experiment is not a new one. French science and technology returned to the centre of the world stage in the 1960s and 1970s thanks largely to the vision of General de Gaulle. According to figures collected by one of the present science minister's cabinet advisers, M. Pierre Papon, French science spending didn't just increase during de Gaulle's rule — it quintupled. In 1958, the French government spent FF1,540 million on research and development; and in 1967 (when de Gaulle resigned) the figure was FF8,836 million. Part of the rise can be accounted for by inflation, but even as a fraction of the government budget, the increase was staggering; from 2.5 per cent in 1958 to 6.2 per cent in 1967.

De Gaulle sought national independence, which among other things implied economic and military independence of the United States. There should be French nuclear weapons; French rockets; French electronics; French energy. And of course, French science both to support this technological development and, not least, to fly as a flag of French pride.

The experiment worked, in most essential areas (electronics still has a long way to go); and in the process science in France was transformed. There were 9,000 researchers in the state sector in 1958, and 21,000 in 1965. (The 1968 university revolution, which came the year after de Gaulle's departure, added even more: the figure was 31,000 in 1969.) This was the age of gold.

As if to confirm de Gaulle's investment, though no doubt entirely unconnected, the first of six Nobel Prizes won by Frenchmen since the war were announced in 1965: those of André Lwoff, François Jacob and Jacques Monod. Monod, however, gave a sour interview to the weekly newspaper Le Nouvel Observateur after his award, claiming that M. Georges Pompidou, de Gaulle's prime minister, was not doing enough for science. ("Pompidou never forgave him for that", says Jacob.) Perhaps it was true that more was being done for physics than biology, though one of those concerned with distributing the money in those days - M. Charles Thiebault, recently president of the Centre National de la Research Scientifique - says molecular and cell biology had a high priority in de Gaulle's programme. Thiebault's figures on French research productivity in the 1970s (see following page) show that the most dramatic increases in that decade came in molecular and cellular pharmacology, a fact which can be traced back, he believes, to increased support in the 1960s.

But how long can such experiments last? By the 1970s, the gold had tarnished. De Gaulle had pushed the national French research and development effort, including industry, from under one per cent of gross national product in 1958 to 2.2 per cent in 1967. Monod seems to have been right about Georges Pompidou, for when he became President the science budget began to fall. By

1980, research and development spending accounted for only 1.8 per cent of the country's gross national product. French science during the 1970s was based largely on the structure and staff given to it by de Gaulle.

Today, the unlikely inheritor of de Gaulle's scientific mantle is the left-wing socialist M. Jean-Pierre Chevenement, not as president of France, but as minister of state for research and technology with his own powerful ministry (something de Gaulle, in fact, avoided setting up). Chevenement, strongly backed by President François Mitterrand, is in effect relaunching Gaullism for science — albeit with a human face. The difference is that Chevenement's programmes are being designed for the people; de Gaulle's were for "France". If the difference seems subtle, that's because it is subtle. There is only a touch of democracy in Chevenement's thinking. His is a planned economy. But it is one, at least, in which the impact of technological change on the fabric of life in France will be taken into account in the development of policies.

Also, and inevitably in 1982, Chevenement's choice of grands programmes differs from de Gaulle's. The new minister does not control defence research (which was 65 per cent of de Gaulle's first research and development budget). So physical science will not be so prominent. In fact, the most advanced and active of Chevenement's plans concern biotechnology, with its spin-off of support for molecular biology, microbiology and enzymology.

The 64 million franc question, however, is whether the plan will work at all. The whole economic exercise now under way in France is a gamble on investment: the exact opposite, say, of British policy. The projected budget deficit of the French government for 1983 is now FF 200,000 million (£20,000 million). Moreover there are structural and psychological obstacles to the further development of science — and in particular, technology — in France. These centre around the strong, historic distinction that has been drawn in French higher education between training (represented by the grandes écoles) and culture (represented by the universities). De Gaulle probably went as far as he could without changing this system substantially. Chevènement, needing to go beyond de Gaulle's achievements, may not have that luxury.

Has France got the money.

IT seems that France is now committed to an immense and breathtaking economic gamble, like a hardened punter throwing all his chips on one spin of the wheel. In direct contrast to the straitlaced grocershop monetarism now the fashion in Britain and the United States, the French solution to the recession, to unemployment and the challenge of Japan is to spend, spend, spend.

Consider the ministry of industry. Capital aid to industry and business excluding the defence industry and support for research and development - has grown 80 per cent this year to FF8,000 million (£800 million). Against such massive increases in direct support to industry, the 29 per cent increase in the government research budget for 1982 looks almost niggardly. Moreover, the increase in spending money - as opposed to commitments to order, but not actually buy, equipment and materials - has risen only 23 per cent, or 9 per cent allowing for current inflation; and since the US dollar has risen 50 per cent against the franc in the past two years, and many materials and much equipment must be bought at dollar prices, some laboratories claim that they are at best maintaining their real level of expenditure. Furthermore, some 25 per cent of this year's new money may be withheld if the economy does not perform as hoped, so there are growing doubts among researchers as to the true value of the "boom".

Nevertheless, Jean-Pierre Chevènement, minister for science and technology, is giving major boosts to certain areas, which must survive the worst of disasters. ANVAR, the Agence Nationale de Valorisation de la Recherche, which seeks to convert research in university and government laboratories into productive industrial innovations, will increase its budget by 76 per cent this year; alternative energy research grows 50 per cent; and aid for the dissemination of scientific information, up 80 per cent.

Meanwhile the budget and foreign trade deficits balloon massively. The total government budget will increase by 28 per cent this year - leaving an estimated deficit of FF95,000 million (£9,500 million). The foreign trade balance (dominated by oil imports) is expected to be in deficit to about FF60,000 million (£6,000 million). For rough comparison, Britain's current account deficit is about 10 times less severe, when oil revenues are subtracted. (Including oil revenues, Britain is in the black to about the same degree that France is in the red.) around: the Mitterrand gamble is a long one.

and the science?

FRENCH science is on the move - upwards - according to figures prepared by the expresident of the Centre National de la Recherche Scientifique, Professor Charles Thiebault, with help from CNRS and the Pascal bibliographic data bank (see table).

Thiebault calculated the percentage of research papers of French (and other non-US) origin in the 286 most-cited journals of Science Citation Index, and compared two years as near as possible to 1970 and 1980. By this measure, all French science except physics increased in literature penetration during the 'seventies. The best single penetration at the end of the decade was achieved by French astronomy: in 1979, 10.8 per cent of the surveyed astronomy papers were French. The best improvement was in pharmacology, from 0.5 to 5.5 per cent. Most of the papers were in English.

By comparison, the United Kingdom suffered a dramatic decline.

As with all such figures, however, the data must be interpreted with caution. The number of French scientists leapt up during the expansion of the universities in 1968-71, so to some extent increased penetration is a measure of increased quantity rather than quality. For example, French mathematics is certainly far better than seems to be indicated by its penetration of the literature. Since 1945, the Fields medal for mathematics - the

"Nobel Prize" of the subject - has gone five times to France, compared with only eight to the United States (which has five times the population). By contrast, in the scientific Nobel Prizes, France has been weak: six since 1945 (two in physics, four in physiology and medicine) compared with

13 in Germany and 35 in Britain.

Praction of papers (%) in major scientific journess								
Disciplines	France	Germany	UX	Japan	Canada			
Mathematics								
1970	3 4	90	10.0	1.0	4.5			
1988	7.2	11 5	6.9	3.3	3 4

Biology								
1970-73	2.3	46	16.0	2 8	39			
1979-80	4.4	50	12 0	4.7	4.6			

Thiebault himself interprets the figures as a good broad measure of the productivity of the community of French scientists, indicating that France is now producing science "at the normal rate". But he is worried about what will happen in the late 1980s. Scientists are most productive in their 30s and 40s, Thiebault believes, and the drastic fall in French recruitment of young scientists in the 1970s may ultimately show through in output.

Read right on from here

In the following articles, there is an Anglo-Saxon look at France in something approaching a logical sequence. But it may not be logical enough for a French man or woman. Logic is a great French strength, but also a weakness. The greatest respect goes to the most abstract disciplines: purest of pure mathematics, the most theoretical anthropology. The schools create this love of logic, and the grandes écoles foster it.

Logic is also linear, and the French certainly love the direct route. Crossfertilization and mobility seem to be foreign ideas. The author of a recent report recommending the establishment of an agency for technology assessment wrote "in France, there are traditional difficulties in thinking in terms of complex systems and networks . . . ".

Careers also are seen linearly. A vogue word these days is filière, which is usually applied to industry: a filière is a whole chain of connections which takes a primary material to its marketable product. There are filière electronique, filière énergetique, and filière what-youwill. Industry is a clutch of distinct filières. It is the same with careers. One follows one's chosen career, with a series of qualifications marking progress and serving to attach one firmly to this line rather than another.

In the following pages, some of these threads are laid out: the line of the grandes écoles, which leads to industry and the ministries, and skims off many of the most able pupils; the line of the universities, still wavering after the "revolutions" of 1968, where most French research is done; and the line of the grands organismes, the big state institutions which fund and control the best of that research.

The new politics of research are outlined on page 299 — the minister for science, Jean-Pierre Chevenement, wishes to push French research and development spending up by 25 per cent in real terms by 1985, to 2.5 per cent of the gross national product. Chevènement may be spending more money and employing more people, but he is also attempting to link a few of the stubbornly separated filières: to link industry with the grands organismes, research with the grandes écoles, thereby seeking greater productivity from French science.

At the same time, Chevènement will be creating some filières of his own: a number of full-scale national research and development programmes, after the style of de Gaulle before him. We sketch one: biotechnology (page 295). Finally, we review two of the most successful existing French technological programmes: space and nuclear energy.

Great schools, great contradictions

THE most extraordinary thing about the French education system is that it is dominated by science, and yet it is inefficient at producing scientists. At the age of 14, children are selected to study for this or that branch of the baccalauréat, or "bac". The most able are groomed for bac C: mathematics and physical science. To do anything else is, by comparison, to opt out of the academic race. Bac C pupils are virtually the only entrants to the grandes écoles, the higher education production lines of the French élite. When bac C pupils go to university, as nearly half of them do, they do better than any other class.

Yet of this leading group, only a minority choose to study science. Have they had enough of it? Roughly one in eight go on to short-term technology courses at "instituts universitaires de technologie". Another one in eight (about 3,000 a year) study science at university. Two-thirds of those who go to university study something other than science.

The contradiction goes deeper. The really ambitious bac C pupil goes on to two-year preparatory classes, cramming schools aimed at the special entrance exam to the grandes écoles, the concours. The preparatory courses are called taupe (and hypotaupe) — that is, "mole" and "hypomole" — for good reason. The work is so intense that the student never lifts his or her head to the light of day. Once a student is successful in the concours, the grandes écoles themselves are a relaxation: a qualification and a good job are almost guaranteed.

What then do these moles learn when they emerge into the grandes écoles? Not "science", properly speaking. The teachers, on the whole, do not do research. There are great variations in coverage, and in quality, but what is called "engineering" dominates. Of 300 or so grandes écoles, 160 are engineering schools. Another 60 are business schools, and another 80 cover miscellaneous arts and occupations. Two or three schools do have substantial research departments, including the prestigious Ecole Normale Supérieure, and so teach science effectively - but only to a few hundred, in total, of the bac C élite. Moreover the science is almost exclusively physical; biology has until recently been largely neglected.

Even the engineering taught by the grandes écoles is said to be too theoretical, too dry and too dated to be good engineering (though there are important exceptions, of course). So what do the grandes écoles teach their students? They teach rigour in argument, and — a practical matter — how to take decisions.

The subjects studied might as well be classics for all the significance they have. The jobs pages of *Le Monde*, the principal French newspaper, are plastered with adverts for *ingenieurs grandes écoles* not

because these are engineers, but because these will be the most intelligent managers. The ministeries of the French state also recruit most of their top staff from the grandes écoles.

The remarkable result is that while French education stresses science from the age of 14, the product is a group of managers and civil servants who could hardly be further from research. The university system, where research is done, is seen very much as second class, and the social distinction is maintained throughout life. The club of the grandes écoles is exclusive, and the damaging consequence is that research penetrates industry far less than it should.

The universities themselves have their own problems. They were not ready for the student population bulge of the sixties, and together with certain social and political factors the result was the transformation of 1968, whose impact—has still not been properly assimilated.

The rise in student numbers was dramatic. In 1960, there were 223,000 students studying in the French universities — which were then arranged as almost totally independent, unconnected faculties specializing in this or that discipline. By

(Plantu, Le Monde)

1968, there were more than 575,000 students cramming into the same lecture halls. "Often there were hundreds at a lecture", wrote one observer, "many of them sitting on the floor right up to the blackboard. Students had to arrive early to get a place". The chalky lectures seemed out of touch with the concerns of youth: the Vietnam war, alternatives to "scientism" and economic growth. The students demanded change, and got it.

The present French universities, apart from ancient establishments like the University of Paris, are largely the creations of 1968. Faculties were grouped into multidisciplinary campuses. Students were given rights in university administration, new courses started, new

First lady at the École Polytechnique: Anne Chopinet graduates in 1972, one of a group of seven who were the first women ever to study there. Now she deals with mineral resources and uranium exploration at the ministry of industry.

universities founded, and new lecturers recruited. Recruitment had been going on earlier, however. In 1960, there were 10,000 university teaching staff from professors through maîtres conference, maîtres assistants, to assistants. In 1967-68, the number had reached 26,000. Some 2,000 assistants were recruited that year. But in 1968-69, the number of appointments was 4,500; in 1969-70, 2,500; and in 1970-71 (slowing down substantially) 800. By 1973-4 the number of teaching staff was nearly 41,000 (where it has roughly remained for ten years). Thus in 1980 there were 41,000 lecturers and 861,000 students, a university system almost exactly four times that of twenty years before, containing a mass of assistants created in one brief five-year period. Throughout this higher education boom, the grandes écoles remained aloof, taking almost constant numbers.

The suddenness of this growth, and the continuing strong position of the grandes écoles, has meant that the universities have found themselves almost entirely detached from the centres of power in France, from industry and from government (which nevertheless keeps them on a tight rein, like an errant child). There has thus grown up a feeling — in part a legacy of 1968 — that the university and its research should not be sullied by contacts with industry. This has become a principle, one which also gives the new university system a feeling of dignity in French life.

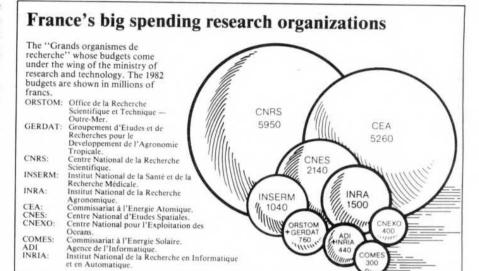

The distinction is even reinforced by law: university staff are civil servants who, in principle, should not seek consultancies in industry; and the universities should not enter into any kind of profitable liaison with a company. Needless to say, the more enterprising universities and staff have set up such links by devious means; but the law sets up obstacles. (One of the most important exercises undertaken by the new

minister of science, Jean-Pierre Chevenement, therefore, will be to remove these legal trip-wires, and the forthcoming "law of research" (see page 289) should do so. But the established suspicion of industry will remain.)

There is also another weakness in the French university system: its relation to research itself. The control and management of French science rests essentially with the grands organismes, roughly equivalent to other countries' research councils, but more powerful and paying more salaries. The grands organismes draw their researchers from the university system, give them better research facilities, remove their heavy load of teaching and administration but - for the moment - give them worse conditions of employment: lower pay and fewer rights, even though they may be working in the same campus, even the same laboratory as university "teacher-researchers"

Most scientists, however, are keen to make the deal — as is evidenced by the nearly eight-to-one ratio of applicants to posts at the junior grands organismes level of attaché (see page 287 for details of the more prominent grands organismes). The grands organismes, plus one or two separate research institutions like the Institut Pasteur (biology) and the Institut des Hautes Etudes Scientifiques (mathematics and theoretical physics) are the heart of science in France.

Now comes the crunch: since grands organismes researchers tend not to teach,

and since they do the best research, higher education is denuded of its leading scientists. So how are scientists trained?

This may become one of the most important issues in French science policy, for with the promised civil servant status for grands organismes researchers, matching that for university teachers, there will be nothing to keep researchers in the lecture theatres but a dedication to teaching. Much is now being made of the catch-phrase "education for and through research", but the means are still being sought to bring it to reality. The grands organismes are now under pressure to play a greater role in education, and they must

take it up if they are to find the scientists they need in future years — but the universities are very wary of such moves, seeing them as an encroachment on the territory.

All in all, there is a lot to be done. The government does seem to be aware of the problem: the minister of education, M. Alain Savary, promises a new law for the universities by the autumn, and he is working in close collaboration with his pushy opposite number in the ministry of research, Jean-Pierre Chevenement. We shall see then if anything substantial and long-lasting is to be achieved with French science.

What Aigrain thinks of it all

THE man who must look most wryly at the present efforts to create a renaissance in French science and technology is Pierre Aigrain, now director of research and development at Thomson CSF, but minister of science under Giscard d'Estaing.

Wryly, because he had begun to push up the science budget in 1981 (not so much as Chevènement in 1982, but the latter's efforts are carried on the tide of an overall 27.6 per cent increase in government spending). Wryly, because the politics of opening science to industry were his own. In some areas Chevènement has even taken on the very advisers that Aigrain used. Chevènement appears to be getting the glory for a policy which, in large part, was established by Aigrain. So what does he think of his successor's plans?

Aigrain is "very glad" about the proposal for a law that would more or less guarantee the science budget for a few years (see opposite). But otherwise he feels there has been a change of wording more than a change of substance. Aigrain clearly thinks that the National Colloquium on science and technology, which drew together scientists and others influenced by their work in a great

jamboree of meetings late in 1981 and early this year, was a marvellous idea, for the real problem of development in France is a matter of psychology as much as one of regulations and budgets; the colloquium demolished some barriers.

However, he is worried about Chevènement's accelerations of scientific recruitment to the grands organismes

Pierre Aigrain — pleased with the "loi programme" but worried about industry

(like CNRS) from 3 per cent of staff per year (under his ministry) to 4.5 per cent. There are enough good people to fill the quota, says Aigrain, but not enough left over to satisfy the needs of science-based industry; and since the security and terms of employment in the grands organismes are excellent, industry is going to have a

hard time reaching the 8 per cent a year real growth in research and development demanded by the new minister.

Education needs an overhaul, and the government is aware of the problem, Aigrain believes, but an education system has a lot of inertia. Moreover, the source of the problem lies in the secondary schools, so change effected there will take ten years to have an impact on research.

The secondary schools overstress the mathematical and physical sciences, are too abstract, and demand too much of their pupils, he says, "so people who would have been quite good physicists and electrical engineers turn to biology to avoid the 'terrorist' attitude of our mathematicians". The result is too many biologists and far too many social scientists.

The grandes écoles, the majority of which teach engineering, also have a lot of drawbacks. They are rather small, and so produce too few engineers. On the other hand, the universities have completely neglected to train people for industry, and although good research is done, little of it is relevant to industrial problems. "What should be done is to improve the university system and its links to industry, and the selection of university students", Aigrain concludes.

Judy Redfearn & Robert Walgate

No union dominance at the CNRS

The minister answers some questions

THE new politics of research and development in France raises many questions, but some are particularly troublesome. How far will Jean-Pierre Chevènement, research and technology minister, go along with trade union demands for democracy in the laboratory? Why does he insist on the importance of French as a scientific language? And finally, what can he do about getting more scientists into industry?

The first question is particularly topical, for the scientific trade unions in the Centre National de la Recherche Scientifique (CNRS), the leading basic research institution in France, have buried their differences to demand union, and only union, representation on the Comité National — the all-important "parliament" of CNRS (see "Pressing problems for Payan", page 293). What does Chevènement think of that Robert Walgate asked him?

The minister says he is at pains to preserve the "effectiveness and openness" of the Comité National, which must play a greater role than before in determining the policies of the CNRS. But he added that although there would be "no question" of giving a monopoly of seats to the unions, the seats should be open to the unions (through election). It would also be a good thing, says Chevenement, if the unions began to concern themselves more with "the quality of research" in their politics, a remark that indicates that he would like the union to broaden their horizon. Nevertheless, says the minister, a union presence "raises the level of debate".

As for promoting the use of French in science, Chevenement says the objective is to help communicate science to the public, and to those who might make use of it in industry, "to maintain the strict link between the French scientific community, and the national community, which would be put under great strain if French ceased to be the language of scientists . . . French must be defended even in areas of research where the rule is to use English."

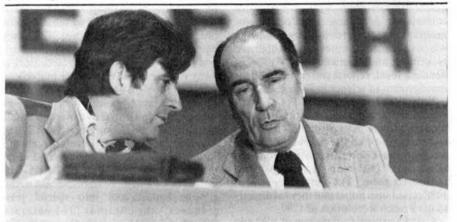

It follows that all French research must be published "at least" in French and, "if possible", in other languages, says the minister. In conferences held on French soil, French must be one of the working languages. A long-term programme must be undertaken to "renew French scientific and technical publications". A government supported publishing house will be set up for this purpose, says Chevènement and there will be "a vast effort" to translate foreign publications into French.

Many have claimed that the cost of such

a programme will make it impractical, but "it will not cost as much as they say" says the minister. The budget for the programme this year is FF 70 million (£7 million). But Chevenement adds that this budget is planned to grow "considerably" in the years to come.

Finally, research in industry will be supported by plans to train 1,500 engineers a year "through research" by 1985, compared to only 500 a year at present. (France produces some 11,000 qualified

engineers a year at the moment, but only a small fraction have training in research.) Particular efforts will be made to train the engineers and scientists needed for the *programmes mobilisateurs*—the special long-term programmes of the ministry, such as biotechnology and electronics. "This is in line with a major policy of training through research that we think will resolve the problems of high-level scientific recruitment, both for the public research organizations and for industry".

"Make France the third scientific and technological power of the world" François Mitterrand (right), President of France, has told minister of state for research and technology, Jean-Pierre Chevènement (left).

A new law for science

ONE law for the military, one for science: the management of the defence budget was foremost in the science minister's mind when he created a "programme law" for science which would define the budget and orientation of his ministry for five years. The ministry of defence employs a series of such laws, which avoid the frequent battles for funds and policies.

The result is the "loi de programmation et d'orientiation", now before the French economic and social committee for comment and possible amendment. The law fixes a government civil research and development budget increase of 17.8 per cent a year in real terms, averaged over the three years covered by the law. Fundamental research gets a 13 per cent per year increase. Jobs in science will be created at the rate of 4.5 per cent of existing positions a year (on average). And support will be given to industry to increase research budgets by 8 per cent a year.

No details are given in the law of how the money is to be spent, which has been taken by some to be a weakness; on the other hand, the ministry sees this lack of detail as a strength, giving it room for manoeuvre.

Moreover, one major financial battle has already been won: in the section on grands organismes the law speaks of financial control a posteriori. Up to now the ministry of finance has held very tight rein on the details of budgets with laboratory directors consequently unable to make even minor changes in spending once the budget for a year has been agreed. Under the new law, there should be more freedom.

This most important section of the law also redefines the role of the grands organismes. They would now have four tasks: to pursue research in every domain; to ensure discoveries are brought to application wherever possible; to spread knowledge; and to educate and train people "through and for" research. The law would also give the grands organismes a better legal framework in which to cooperate with industry. This would allow CNRS, for example, to join with and even hold shares in sister companies.

Researchers in the grands organismes, however suspicious they might be of industry should welcome the provisions in the law for a new contract of employment which would give them something approaching civil servant status.

Other important provisions in the law are an emphasis on regionalism and an identification of the main programmes of research to be developed by the ministry. These are: the rational use of energy and new sources; biotechnology; electronics; research in cooperation with and for the Third World; research on working conditions and the impact of new technologies; the promotion of French as a language of science; and technologies related to French industrial development not included in the above (with the exception of nuclear engineering).

Science — the next revolution?

THE Mitterrand government wants to make its mark on history. So for what will we remember the minister of state for research and technology, Jean-Pierre Chevènement?

Quite likely for what the newspapers dubbed the "States General" of science, an apparently formless meeting in January this year of some 3,000 French men and women representing almost every nook and corner of French science and technology. This National Colloquium on Science and Technology was merely the culmination of a large series of regional meetings — the Assizes Regionales — which took place the previous October and November, and generated 200,000 pages of detailed, local, reports and criticism on the management of science in France.

Why "States General"? Les états généraux were a feudal institution, last used by Louis XVI in 1788, in which reprentatives of all the parishes of France were called to Court to make their concerns known to the king. Louis himself misjudged them. The States General of 1788 raised such hopes that they led directly to the French Revolution of 1789.

So the National Colloquium of 1982 was a "States General" of science. That's not to suggest that next year there will be a revolution — but great hopes and fears have been raised among the scientific masses, and Chevènement now has to ride this flood or be submerged. Already certain trade unions, strong in French science, are threatening a struggle (see below). Whatever happens to Chevènement, he will be remembered for having created the National Colloquium. Pierre Aigrain, Chevènement's predecessor as

minister of science, clearly regrets that he did not think of the idea himself. . . .

So what are the main currents at work? It's not possible here to do justice to the 200,000 pages which are the main force of the colloquium. But here are a few individual views.

Take Professor Louis Lliboutry, for example, a world-renowned glaciologist with a position at the University of Grenoble and a laboratory supported by the Centre National de la Recherche Scientifique, (the major basic science organization in France). His subject is not one of the current fashions; glaciology does not have much impact on technology and the French economy; the laboratory is away from the centre of power in Paris.

Yet Grenoble is an excellent place to do glaciology, says Lliboutry — he can be at Mont Blance in an hour by car - but he felt this subject had been neglected by CNRS. "Our budget increases have not kept up with the cost of living", he said: and whilethe real money had shrunk, CNRS had shifted more and more resources out of the general budget and into special pro-grammes, the Actions Thématiques Programmées (ATP). So in the past if your research did not fall within the framework of an ATP, you were neglected. In fact the exercise of raising cash had become largely one of convincing the relevant committee that your research fell within this or that ATP. For glaciology, one could sometimes make contact with the physics of tectonic plate movement or climatology, for example. "The people in the committees are the most noisy, but not necessarily the most brilliant", said Lliboutry.

There is an alternative now, however, on

the ATPs — whose use increased greatly under Giscard d'Estaing's science minister, Pierre Aigrain. That's that they provide an opportunity for new researchers and new groups to draw on CNRS funds, in competition with established laboratories.

Unfortunately for Lliboutry and other laboratory directors who share his views, the emphasis on ATP increases slightly under the new government: CNRS funds for ATP rise 41.5 per cent this year compared with last. General programme support in CNRS will also rise, but less strongly: 36.8 per cent. Funds for big equipment (costing more than FF 100,000-£10,000) increase least: 10.5 per cent.

However, another of Liboutry's worries may be dealt with by the research "law", the "Loi de programmation et d'orientation" (see page 289) which is currently receiving the attention of the economic and social committee of the French Assembly. The problem is flexibility in the use of funds.

"We lab directors have no free money" says Lliboutry. This is the real obstacle to good research — what Lliboutry calls "the Kafkaesque rules for finance". These are imposed by the Ministry of Finance, but also by CNRS itself. For example, suppose Lliboutry asked for FF 100,000 for glaciology equipment and another FF 100,000 for general research expenses, for a project within some ATP; and suppose that ATP committee awarded only the latter FF 100,000 but ignored the equipment request. Then Lliboutry could not divide the sum 50:50 as he might wish.

This might change — at least in so far as the Ministry of Finance is concerned — if the *loi* is passed by the assembly, for the law will loosen constraints of this kind on CNRS. How far CNRS will choose to devolve this new freedom to its laboratory directors, and how far it will want to keep control through its central committees, is undecided, however.

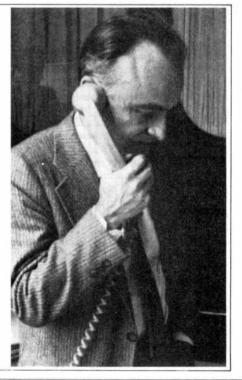

Jean-Jacques Payan, the recently appointed director-general of CNRS, would in fact be well-advised to devolve this new power (if, of course, the Assembly approves it). Lliboutry's complaints are far from unique; they represent a widely-felt unease in the regions of France that the control of science has always been too hierarchical, too Paris-based, and that the minister for science, Jean-Pierre Chevènement, while paying lip service to "democracy", has in fact such well-formed plans that Paris control will continue as strongly as before.

"We need a local esprit d'enterprise in small science, with the freedom and the power to make judgments locally", Lliboutry suggests, with decisions up to a certain level taken by local laboratory councils. Many speeches and papers at the Assizes Regionales and the National Colloquium made the same or similar points. The loi, it seems, will set up regional science committees charged with esta-

Colloquium into law

PIERRE PAPON (right), professor of physics in the University of Paris, is a prominent member of the science minister's cabinet. Papon was responsible for assessing the sometimes diffuse results of the National Colloquium on Science and Technology, and putting these conclusions into effect in the new law for science (see page 289).

Papon identifies four principal effects of the colloquium on the law: on regional development (regional councils for science were proposed at the colloquium, and have found their way into the law); the principle of education through and by research — which is to say that the grands organismes should have a role in education as well as the universities; other improvements in the training of scientists; and the recognition of research as a career so a researcher could expect similar conditions of employment in different organizations, to allow more mobility.

The CEA research centre at Grenôble, on the borders of the French Alps. The dome of the Institut Laue Langevin reactor building can also be seen on the left. The area includes many important laboratories and represents the largest concentration of physical science in France outside the Paris region.

blishing regional science policies and spending a certain amount of money, but it is unlikely that these bodies will have much effect on basic science.

The opposite concern — expressed at the other end of affairs, in Paris - is that there is a degree of rigidity in the system of science management, caused in part by the existence of laboratories whose directions are difficult to shift. Although in principle research posts with the big three research organizations - CNRS, INSERM (for medical science), and INRA (for agriculture) - are contractual, and assessments of performance of staff at laboratories are made regularly, laboratories are very rarely closed down and people almost never fired. Professor Charles Thiebault, who resigned last year as president of CNRS over a conflict with science minister Chevenement, says that of the 1,200 or so CNRS laboratories (one third of all university laboratories), perhaps one or two were closed each year and staff were moved on to new work. Moreover, a new contract for all research workers, contained in the loi, will give researchers even more security, matching that of civil servants.

Professor Michel Petit, director of INAG, which is effectively a wing of CNRS concerned with managing astronomy and geophysics, points to another stiffness in the joints: applicants for CNRS posts specify which laboratory they wish to join. So although assessment is made nationally, keeping standards up, students tend to return to their old professor's laboratory, reducing mobility.

These are directors' complaints, however. Down at the grass-roots, some rather more anarchic notes are being struck. At the Strasbourg Assize Regionale, for example, there was a strong call for laboratory directors' posts to be made fixed term — perhaps four years — to stop one man gaining lifetime control over a sector of research, and allow a few new

flowers to bloom occasionally.

Even at the Institut Pasteur in Paris, a world-renowned centre for microbiology and molecular genetics, there is a degree of revolt. Laboratory directors should be continuously assessed, some of the younger researchers say. There is a tendency for group leaders and laboratory directors in France to stop doing research and become full-time politicians, they complain - quite unlike the United States, where group leaders might spend time rooting for money but do not neglect the life of their groups. Jacques Monod, the famous director of the Pasteur in the late 1960s and early 1970s, is said to have been an exception. Certainly François Gros, the previous director of the Pasteur, has taken the political path: he is now science adviser to the Prime Minister, Pierre Mauroy.

The myth of the "savant", the wise man to whom all possible respect is due, is also too strong in France for the health of science, young researchers say. Strangely for the country which once slaughtered its aristocracy, there is an almost servile respect for these intellectual aristocrats.

According to Professor Bernard Jacrot — himself a potential savant, who directs the neutron scattering outstation of the European Molecular Biology Laboratory at the Institut Laue Langevin, Grenoble — the problem starts in the secondary schools. "As soon as a pupil tries to be individual, he is stamped on" he says; and this reflects itself in the structure of the French laboratory, which is very hierarchical "leaving little room for originality".

Thus there is a need to give younger researchers their head, perhaps against the will of the all-imposing director, and this is a theme which the powerful French scientific trade unions have taken up with enthusiasm. But there is a difference between flattening the pyramid a little, and turning it upside down.

However, one of the clearest democratic

Big physics

THE Commissariat à l'Energie Atomique (CEA) has a civil research budget for 1982 of FF5,260 million, exceeded only by that of the Centre National de la Recherche Scientifique. The budget is high not so much because the CEA supports a lot of researchers (nearly 9,000 at CNRS, only 900 in fundamental research at CEA), but because the bulk of CEA research is in the applications and development of nuclear energy. The fundamental science is also expensive - reactor physics, accelerator physics, nuclear fusion and high energy astronomy. However, CEA researchers also work in condensed matter and materials science and chemistry and biology (using isotopes). The fundamental research budget of the CEA in 1982 is FF 1,292 million.

The CEA works in strict liaison with the other grands organismes on many joint programmes (such as the nearly-completed nuclear accelerator GANIL, in conjunction with IN₂P₃) and with international organizations such as the European Centre for Nuclear Research (CERN) and the Institut Laue Langevin. Its principal research centres are at Saclay, Caen, Fontenay-aux-Roes, Grenôble, and Cadarache.

indications of the wishes of basic scientists has come from an internal survey conducted by CNRS. Professor Guy Aubert, director of the Service National des Champs Intenses, was charged with collecting the contributions of CNRS staff to Assizes Regionales and related meeting throughout France. Five main themes emerged, said Aubert.

First, people were worried that Mitterrand's and Chevenement's committment to regionalism would mean that peer assessments and appointments would be made and decided regionally. This was thought to be a bad thing, because a critical mass of assessors could not be reached and local savants might become even more influential.

Second, there was strong pressure for more "democracy" in the laboratory — the banner which the unions are flying. There should certainly be consultation through a laboratory council, including administrators and technicians, over major developments. And there should be elections "even, and perhaps especially, of the laboratory director" (Aubert sums up).

Third, it was felt that there was more room for research in the social sciences — not just more money for the field, but a re-orientation of priorities towards current political, economic, and social concerns in France. This view is certainly shared by Chevènement, as the resignation of Charles Thiebault (mentioned above) as CNRS president was the result of the

minister's efforts to force a social scientist of exactly this persuasion onto CNRS, as social sciences director.

Fourth, there was much puzzlement over the role and relationship of all the big organizations which control and fund science in France. "It seems to people in the laboratories that these things are not clear" says Aubert. It is possible to obtain money for a given subject from many different sources, under different rules, and career requirements under different heads for essentially the same work can be quite distinct. This leads to a confusion of careers and priorities, and a reinforcement of the feeling that policy is decided behind closed doors according to unknown rules. Chevènement has said he seeks "transparency".

The situation seems to be most extreme for the medical sciences, and basic sciences bordering on medicine — going as far as molecular biology. Here there are the CNRS, whose major sector is life sciences; INSERM, the Institut National de la Santé et de la Recherche Médicale; the Mission de la Recherche of the Ministry of Universities; the universities themselves; and the teaching hospitals. Dr Jean Dausset, for example, is at the Hôpital St Louis in north Paris. He is also head of an

INSERM unit. And co director of a CNRS laboratory. Or take Professor Pierre Chambon. He is a professor at the Université Louis Pasteur in Strasbourg, and head of an INSERM unit and director of a CNRS laboratory, under the same roof. It is good to know that the new director of INSERM, Professor Philippe Lazar, and the director of life sciences at CNRS, Professor Roger Monnier, aim to resolve the issue.

The fifth and final concern detected by Aubert's review of CNRS papers to the colloquium and its tributaries was over the matter of contracts. As one foreign observer and francophile put it, the urge for security is extreme in France (so the trauma of two million unemployed can be imagined). So unions have been pressing, essentially, for tenure, and a strict demarcation of jobs; conditions of work like those of civil servants (the goal, it seems, of every Frenchman and woman); and an "open" assessment of researchers.

Some of these demands the unions will achieve in the "loi"; others they will not. But the unions are pressing harder on this left-wing government than they did on the previous right wing one, much to the socialists' embarrassment; and what the result will be is anyone's guess.

strengthen existing ones.

It is perhaps unfair to make selections, but some of the outstanding regional centres are Grenoble and Lyons (for physics), Strasbourg (molecular genetics), Toulouse (biotechnology and space science) and Marseilles (immunology). The unique technological University of Compiègne — it can probably be counted just outside the Paris region — is also outstanding in enzymology, particularly as it relates to biotechnology.

The largest sector of the CNRS budget for 1982 goes to life sciences (25.5 per cent), which looms larger than it might because some of the heavier expenses of big science are borne by or shared with the Commissariat à l'Energie Atomique (for nuclear physics) or the Centre National d'Etudes Spatiales (for satellite-borne astronomy). Even so, life sciences are also supported by the Institut National de la Santé et de la Recherche Médicale — whose budget exceeds that of the life sciences sector of CNRS though employing fewer researchers.

Other sectors of CNRS are chemistry (15.7 per cent of the 1982 budget), nuclear and particle physics (12.9 per cent), earth, atmospheric, ocean and space sciences (11.8 per cent), mathematics and basic physics (11.7 per cent), social sciences (8 per cent), physical sciences for engineering (7.9 per cent), humanities (5.5 per cent), and interdisciplinary programmes (1 per cent).

CNRS is in fact organized as a "group" of three bodies: CNRS proper, plus INAG and IN₂P₃. The latter are the Institut Nationale d'Astronomie et de Géophysique, and the Institut National de Physique Nucléaire et de Physique des Particules, and they manage the parts of the total CNRS budget concerned with those fields. INAG and IN₂P₃ are loosely controlled by the CNRS directorate, which selects the INAG and IN₂P₃ directors (from lists of "at least two" names proposed by these bodies) and channels funds to the two

CNRS — the core of research

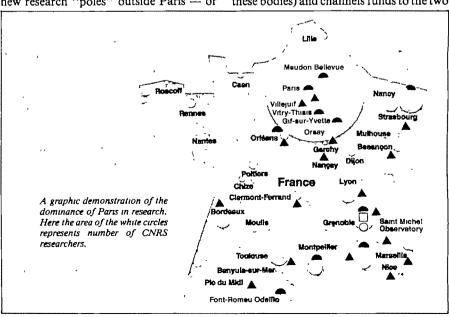

THE Centre Nationale de la Recherche Scientifique (CNRS) has FF 6,000 million to spend this year — about £600 million, including salaries. CNRS attracts and controls the cream of most basic science in France — with the exception of mathematics, which has a very strong French historical tradition and leads a more independent life. With that exception, the goal of most aspiring basic scientists in France is to join a CNRS group or laboratory — a goal which has become even more attractive now, since the new government has increased scientific recruitment to CNRS and its junior partners by 50 per cent, and now that CNRS scientists are promised essentially civil service security, pensions and other rights.

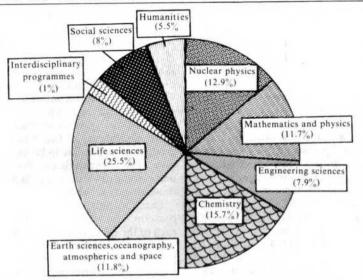

Entry to CNRS is by examination and interview. In 1980, for example, around 3,000 young scientists applied to join CNRS. Most of the 3,000 had just completed a troisième cycle (something between a master's and a PhD degree) at a university; 425 of them were selected as attachés on a four-year trial, after which, according to the 3 per cent recruitment then in force, some two out of three might have expected to receive a full-time appointment as chargé de recherche. With 4.5 per cent recruitment, possibly all of this bunch will be lucky

CNRS now employs 23,320 people, of whom 8,970 are researchers, distributed in more than 1,200 laboratories. More than 150 laboratories are fully controlled by

CNRS (*laboratoires propres*), and another 250 shared with another organization, often a university (*laboratoires associés*).

The laboratories are distributed all around France, but by far the largest single geographical group is formed by Paris and its immediate locality — something which simply reflects the unusual dominance of the capital city of France over the rest of the country, in all sectors of life. However, CNRS has set up regional administrations, with a certain degree of power, and the new government is making an effort to identify new research "poles" outside Paris — or

How the 1982 CNRS budget is being divided up. Life sciences get the lion's share. "Big science" is not as prominent as might be expected as budgets are shared in these subjects with CEA and CNES.

bodies. This year INAG receives FF 115 million, IN₂P₃ FF 576 million from within the CNRS budget. The structure is said to make the management of "big science" easier; certainly, battles over funds for expensive equipment are fought at a higher level in the CNRS hierarchy than might otherwise be the case.

The total CNRS group budget of FF 6,000 million represents an increase of 25

per cent over last year, a general increase which hides even larger rises in some sectors. General programme support and small laboratory expenses has risen 36 per cent from around FF750 million to over FF 1,000 million. Salaries take the biggest single chunk: FF 3,900 million. Increases over 1981 are smallest for large equipment and computers (just over 10 per cent). Against these increases weigh the current

inflation figure of 14 per cent; the increase in the dollar against the franc (up 30 per cent over 1981); and the freeze on FF 150 million of CNRS funds (its share of the 25 per cent new money freeze — see first story).

New posts have also been created: 447 researchers and 193 engineers, technicians and administrators.

The new funds are not distributed equally among all research sectors supported by CNRS. The biggest fractional rise goes to an interdisciplinary programme of solar energy and primary materials (PIRSEM), which will get FF 10 million, over three times as much money as its predecessor PIRDES.

Besides that exceptional case, applied physics (physical sciences for the engineer) is most favoured: it receives a 40 per cent rise. Life science gets 38 per cent, earth science 36 per cent. Life science gets the biggest share of the new research posts (127) but then it also has the biggest share (2,500) of the total research staff of CNRS. The budget increases will be used for four principal purposes. First, to re-equip laboratories to "bring their means back to an internationally competitive standard". General laboratory spending suffered a severe decline between 1972 and 1980, say CNRS staff. The previous science minister, Pierre Aigrain, won a substantial increase in the general science budget in 1981 (8 per

Pressing problems for Payan

THE major issue facing the CNRS director-general, Jean-Jacques Payan, and president, Claude Fréjacques, is the reorganization of CNRS — to which the new government and CNRS directorate are committed.

At present, CNRS is structured around a remarkable scientific parliament called the Comité National, which consists of about 1,000 people, roughly two-thirds of them elected every four years from CNRS laboratories and groups and onethird nominated by the government from among scientists, industry and the administration. Researchers, engineers, technicians and administrators are all represented. The Comité is divided into 41 sections according to discipline. In spring these sections advise on individual careers and promotions, and in autumn they consider the prospects of groups and laboratories.

This advice passes to the eight scientific directors of CNRS, who are usually career scientists who spend a period of 4-8 years on part-time leave from their posts to direct a sector of CNRS activity; and then to the "double head" of CNRS, the director-general and president. Ultimately, major decisions are taken by the governing body of CNRS, the government-nominated Conseil of which Fréjacques is president.

To those interested in increasing "democracy" in French science — which means effectively reducing the power and influence of the scientific directors of CNRS and, at the local level, of laboratory directors — the Comité National plays a central role. The scientific trade unions would like to increase their control and influence over

Payan (left) and Fréjacques face the unions

the parliament. Commensurately, it is felt that the powers of the parliament itself should be increased.

A struggle is taking place between these unions and the directorship of CNRS. The unions demand that nobody be elected to the *Comité National* unless he or she is accredited by a union — which represent mostly technicians, engineers and some younger researchers. Payan has sent a letter to laboratory directors to warn them of the threat and ask for their advice. One senior scientist cabled Payan to say he would resign all his CNRS

functions instantly if the unions were granted such power — and his reaction may not be untypical.

Professor Payan himself is shocked by the union militancy. He said recently that the thorough-going dialogue now under way in CNRS touched all levels, and that CNRS old hands had not experienced such a thing for a long time [since 1968, perhaps]. But, said Payan, whereas the union position against the previous rightwing government had understandably been "the most extreme possible", now was the time for a more comprising attitude. Was the socialist government not, after all, on the same side?

A second important — but less pressing — issue facing Payan concerns the relationship between CNRS and the universities. Under the previous government, CNRS was under the authority of the Ministry of the Universities, but now it is controlled by the Ministry of Research and Technology. Since CNRS already creams off some of the best scientists from education, this shift has led the universities to fear a deepening of the class divisions between university and CNRS laboratories.

This fear is further increased by plans to give CNRS a role in the education of researchers. But, says Payan, a break between the universities and CNRS would be a bad thing. CNRS will cooperate with the universities, he says — but, on the other hand, the universities have a long way to go . . .

cent in real terms, he claims), and this year that trend is accelerated to 25 per cent in real terms.

Second, the aim is to bring to fruition certain plans for large machines — the heavy ion nuclear accelerator (GANIL) and a French dedicated 800 MeV synchrotron radiation source, Super-ACO, at Orsay (in collaboration with the Commissariat à l'Energie Atomique, the Ministry of Universities, and the Université Paris-Sud). Increased support will be given for the reactor Orphée and the trinational high flux neutron beam reactor at the Institut Laue Langevin in Grenoble.

Third, new themes of CNRS support are to be established, particularly through the special programmes called Actions Thematiques Programmées (ATP) under which CNRS laboratories and groups compete for extra money available for work directed to particular objectives — which are becoming increasingly technological. This year ATP cash has crept up to nearly 10 per cent of the research money otherwise available to CNRS laboratories.

Finally, FF 8 million have been set aside for a programme of so-called "young groups", which is designed to give younger researchers a chance to create their own groups earlier than would otherwise be the case. The programme also gives CNRS the chance to go head-hunting in some of the smaller universities for new talent. The name "young groups" may be a bit misleading, however: the eight "young" group leaders recently selected by the life sciences sector of CNRS are all about 40 years old. "We hope we can bring the age down somewhat next year" said a CNRS spokesman.

Medicine hot, agriculture cool

CONTRASTED with the scale of the CNRS. the institutions which support health, medical and agricultural research may seem small, but they have a significant impact on research. INSERM, the Institut National de la Santé et de la Recherche Medicale, supports 1,500 researchers (compared with 2,500 in the life sciences sector of CNRS alone). Even so, this is over a third of French biologists, and the means at INSERM's disposal are not negligible: over FF 1,000 million this year. Since the CNRS life science budget is just under FF 1,000 million for nearly twice as many researchers, INSERM scientists can count themselves rich.

INRA, the Institut National de la Recherche Agronomique, is also substantial — although until recently it had appeared to have been neglected by the new government. INRA has 200 researchers and a 1982 budget of FF 1,400 million. INRA is unusual in being highly decentralized, as befits an agricultural agency, with laboratories all over France and also in Corsica and Guadaloupe.

INRA politics, for the moment, are relatively quiet: INRA's director-general, Jacques Poly, has not yet felt obliged to resign over some difficulty or other with the new minister of science — unlike his former colleagues at CNRS and INSERM, who did just that. But perhaps that is because the ministry has hitherto paid little attention to agriculture. Earlier this month, however, the establishment was announced of a new department at the ministry of research and technology, to be concerned with agriculture and food.

Chevenement appears to have noticed that the agroindustry employs 3.5 million workers, and that its activities concern every consumer in the country.

The new department will assess the present state of research and development in this area in France; define priority research areas; stimulate relevant research in small industries and businesses; extend the links between INRA and industry; establish the needs for training and recruitment; and take account of the needs of developing countries.

What Professor Poly makes of this has yet to be seen, but meanwhile the new director-general of INSERM, Professor

Lazar - back to the watering can?

Philippe Lazar, is settling in after his predecessor's resignation. That gentleman, Professor Philippe Laudat, was very oblique about his reasons for resigning, but the speculation is that he feared that his efforts to concentrate INSERM funds on the best groups, so avoiding what he described as "an even sprinkling" of money regardless of quality, would be reversed by the new government. As what Laudat identified as "best" often meant groups working in molecular biology, INSERM researchers in that area are worried.

For Professor Lazar, if anybody, would be the one to apply the politics of Chevenement to INSERM: he was rapporteur for the National Colloquium of Science and Technology in January. So what does he plan to do?

Laudat certainly had trouble with the scientific trade unions, with his determination, as he put it, to open up INSERM research; and Lazar will clearly be more sympathetic to union views. Lazar sees no reason to be so selective with basic research money as was Laudat, because research funds for all basic science are guaranteed to rise 13 per cent in real terms (according to Chevènement's forthcoming law).

"We should try to mobilize almost all research units" says Lazar, "and be a little more confident in the ability of all groups". It is possible to be too elitist, he says. How is one to detect which research unit is going to be successful, as opposed to those already at the top?

Lazar intends to apply a policy of a posteriori, rather than a priori assessment: each of the INSERM units will be expected to present a programme every two or three years in which it expresses its needs; INSERM will then respond. This will save laboratory directors time in their constant efforts to raise money. Each unit will be assessed at this one time by INSERM's eight specialized committees and scientific council, which will give advice on the closing of certain units and the opening of others. But the specialized committees should "follow each laboratory more closely and interfere more".

It should be easier than at present to change the directors of laboratories, says Lazar. As thing stand, a director is appointed for six years — after which he or she is assessed and, almost without fail, reappointed. "The general rule should be that a director should change", says Lazar.

Lazar also feels that the links between the INSERM administration and its scientists are too weak, and he would like to make use of the 225 committee members more than the present twice a year; and he wants to try to improve INSERM's links with the outside world, including CNRS, the Institut Pasteur, the universities, and institutions beyond France.

CNRS and INSERM

Lazar would like particularly to rationalize the overlapping relationship with CNRS, a desire shared by CNRS director of life sciences, Professor Roger Monnier. Sometimes both INSERM and CNRS support the same laboratory in different ways, and neither knows what the other pays. Lazar favours joint committees set up between CNRS and INSERM.

Of molecular biologists relying on INSERM grants, Lazar says "they may be afraid but I am not". Molecular biology will receive "at least 13 per cent" in real budget rises in coming years — as a basic science - and in so far as the work is linked to biotechnology, nearer 30 per cent. For Lazar will countenance certain programme mobilisateurs which will receive more than the average attention. Biotechnology will be one; also the social sciences of health care. Clinical research, generally thought to be weak in France, will also receive special attention, by "opening it up to other research". Lazar intends to hold a meeting to illuminate that issue.

gearing up Biotechnology -

BIOTECHNOLOGY - including the most basic molecular biology - is to be one of the principal axes of M. Chevenement's French technological revolution. Moreover it is the first of his ministry's programmes to get off the ground, because its main points are identical to those followed by the previous government. This is not least because the biotechnology adviser to the previous government now spearheads Chevènement's biotechnology department at the ministry. He is Professor Pierre Douzou, a well-known microbiologist at the University of Paris. The only obvious change from the earlier policy seems to be the fivefold budget increase.

The main weaknesses in French biotechnology have been identified as a woeful lack of microbiologists, a poor system for training genetic engineers, too little work on plant cell biology and weak links between the worlds of research and industry. The genetics of nitrogen fixation is also thought to be poorly represented in France; and lastly, the French pharmaceutical industry is particularly weak in the antibiotic market, and so has little experience in the sophisticated fermentation technologies that antibiotic production requires. On the other hand,

France can boast some world-class groups in molecular biology, particularly at the Institut Pasteur and the University of Strasbourg. The lack of microbiologists is perhaps surprising in the country of Louis Pasteur, but just as in other countries, French biologists have followed the trend towards concentrating on "laboratory" species such as Escherichia coli. To correct the trend, CNRS is planning to set up new groups or laboratories working with species such as Pseudomonas or Actinomyces, and, they say, they are ready to import the right group leaders from abroad. French universities are also preparing to establish professorships in microbiology. Also, plans are almost complete at CNRS to establish a new laboratory of plant genetics in Strasbourg, at a cost of around FF40-50 million, which will employ 100 scientists.

At the Institut Pasteur in Paris construction is going ahead on a new building devoted to biotechnology, to open in 1984-85, according to a decision taken by the previous government. Among other things the building will provide facilities for 5-10 litre fermentation trials and will have a laboratory for the development of

hybridomas.

Science and the scientific are chic right now in France: witness this advertisement for DNA cream from a French magazine.

At present the strong poles of CNRS biology with an impact on biotechnology are at Strasbourg (basic molecular biology and plant science), the Institut Pasteur (all fields), Toulouse (selected by Aigrain to be a special centre for biotechnology), Marseilles (laboratories of immunology

The Pasteur leads the way

THE Institut Pasteur, founded by Louis Pasteur in 1888, three years after his development of an antirabies vaccine, became and remains one of the most important biological laboratories in France; and now, it is also taking a leading role in the development of French biotechnology.

This is happening both at the political and practical level. François Gros, the previous director, has taken a deep interest in biotechnology, and in his last three years as director (he resigned at the end of last year) had begun a slight shift of the Pasteur away from human and animal pathogens (its traditional interest) towards microorganisms of potential economic importance. Now he has become science adviser to the Prime Minister, Pierre Mauroy, where he has considerable influence. Moreover, the National Colloquium on Science and Technology, the great conference of scientists and public that has been one of Chevènement's most imaginative achievements, was Gros's idea. Gros organized and chaired the colloquium, so endearing himself to the new minister of science as well as the Prime Minister.

On the practical side, the Pasteur is now seen in government circles as an excellent model of the combination of fundamental research with industrial and medical development, a kind of mix of priorities which can be traced directly back to the inspiration of Pasteur. The Pasteur has a hospital. It has research which reaches the most fundamental levels of biology (three of the six French Nobel Prizes since the war went to the Pasteur). And it has three distinct ways in which it tries to exploit its research.

There is Institut Pasteur Production, which has a first call on potentially profitable discoveries at the Pasteur; Groupement Génie Génétique (G3), which seeks directly to develop profitable ideas, which it would then license to industry; and a highly differentiated and active system for linking Pasteur staff with industry, making a profit for the Pasteur and aiding the biotechnology industry at the same time.

The latest effort to be announced is a massive trial of a new vaccine against hepatitis B, produced by Institut Pasteur Production, on 200,000 Senegalese children, in conjunction with the Institut Pasteur (Dakar) which is one of the 26 institutions around the world linked to the Pasteur (Paris). Nine out of ten adult Senegalese are infected with the virus, it is estimated. If the trial is successful, there is a big world market for the vaccine.

The Pasteur is also gearing up to train the bioengineers that France will need. Special training will be given to engineers emerging from certain grandes écoles. Links have been established so far with Polytechnique, Centrale, Mines, and Ecole Nationale Supérieure de Physique et Chimie de Paris.

The original Institut Pasteur building of 1888. Pasteur's tomb (see cover) is on the site.

and bacterial chemistry), Compiègne (enzymology and enzyme fixation) and to a lesser extent, Lyons and Montpellier.

Douzou outlines the principal objectives of the ministry as first, to improve training and education in the field; second, to transfer information more efficiently from the laboratories to industry; and third to establish "a multitude of sites" in France as small technology centres, which would embody perhaps four or five researchers, several engineers, and technicians, each working on some pilot scheme. These technology centres should be encouraged in industry as well as in the public sector such as CNRS and INSERM, says Douzou.

In that public sector, Chevènement has said that such laboratories would be judged by the patents achieved, by licences sold to industry and by their general impact on the industrial sector rather than by their scientific productivity *per se*.

However, development work in biotechnology can be very expensive, and France is certainly willing to consider international agreements and programmes at that level. They should be bi- or trilateral and specific, however, rather than conducted through an intermediary like the European Commission in Brussels.

Industry cloning

FRENCH industry boasts a handful of main actors in genetic engineering. They are Transgène, a venture company with a small amount of government support based in Strasbourg; Genetica, a genetic engineering wing of the chemicals giant, Rhône-Poulenc; G3, a group based at the Institut Pasteur in Paris and supported by government money through CNRS, INSERM and INRA and (51 per cent) by the Pasteur itself; and the nationized oil company Elf Aquitaine. Elf is to set up a FF100 million biotechnology laboratory in Toulouse, and through pharmaceutical subsidiary Sanofi it has a 51 per cent share in Institut Pasteur Production, the company with first claim to the development rights of Pasteur Foundation discoveries.

None of these companies except Institut Pasteur Production (which is a an older company with a strong interest in vaccine production) yet has a marketed product, and all are keeping their plans fairly close to their chests. But Transgène, at least, is known to have commissioned reports on the microbial extraction of minerals from sea water and to be considering a special effort on plant cells - stimulated by CNRS plans to make Strasbourg a focus of plant genetics. Transgène's director, Jean-Pierre le Coq, is also looking closely at what the new biology can do in traditional biological industries such as food processing - where, he says, the field is huge and the competition less.

Telecommunications — late start

FIVE years ago, the French ministry of telecommunications, PTT, launched an ambitious plan to improve the services offered by the public telephone network. Since then, massive investment has increased the number of telephone lines from 7 million to 16 million. When he presented his budget to the assembly earlier this year, Louis Mexandeau, the new PTT minister, indicated that he wishes to continue the modernization albeit at a slightly slower rate. He is looking for a further FF 25,000 million a year for the next five years to give a telephone to everyone who wants one by 1985.

As PTT admits, the success of the modernization so far is partly due to the initial small size and poor state of the telephone network. France has been able to opt for the latest technology and avoid the problems inherent in modernizing an out-of-date, yet extensive, system. Hence, for example, France has been able to move over to fully electronic exchanges move rapidly than some of its European neighbours. The plan now is to digitize the network fully by 1990.

To achieve its goals, however, PTT has had to lean heavily on industry. Although the result has been to increase the international competitiveness of the French telecommunications industry, there have been problems along the way. Pierre Aigrain, former science minister who has now returned to his old haunt Thomson CSF as research director, mentions the difficulties caused three years ago when PTT changed suddenly from installing partially to fully electronic exchanges.

The switch meant that Thomson had to reduce its workforce, a task-it has still not managed to complete. Thomson was also at a disadvantage because, unlike its competitor, CIT-Alcatel, it did not receive state help to develop electronic exchanges. PTT supported development in its own research centre, the Centre National d'Etudes des Telecommunications (CNET), and then licensed the product for manufacture by CIT. The CIT product works well, but Thomson is still having software problems.

(The PTT supports most of its research on electronics at the CNET laboratories in Grenoble, which, like the laboratories of CNRS, have been asked to step up the number of researchers employed by 4.5 per cent a year. The ministry of research and the PTT now want the Grenoble laboratories to develop into a major centre that will drive not only telecommunications but also the broader electronics industry.)

Switching to optics

The French have also been fortunate in their choice of technology. By choosing a time division switching electronic exchange, they have suffered fewer technical problems than say Britain with its choice of System X. But installing

electronic exchanges is just the first step in PTT's vision of transforming the network into a modern system for digital rather than analogue transmission.

Like its European neighbours, it is nibbling vigorously at the bait of optical fibres. Thus a 12 km optical link has been installed between two telephone exchanges in Paris and two more links are planned.

Optical fibres are still too expensive for widespread introduction, largely because the signal has to be boosted at regular intervals of about 30 kilometres. The PTT will be waiting until the price comes down to about FF1 per kilometre. But Saint-Gobain and Thomson CSF seem confident that the market will expand soon. Recently, they formed a joint company, Fibres Optiques Industries, with Corning Glass, to manufacture 10,000 km of optical fibres a year, half planned for export.

Optical fibres are also being connected to 2,000 households in Biarritz in the south of France for an experiment, beginning in 1983, that will give each household access to new telecommunications services such as videophone, videotex and cable television, via a telephone linked to an ordinary television screen. A further experiment to bring cable television via optical fibres to the people of Lille is also planned. The aim is to test the usefulness of new technologies and the information they bring to individuals and businesses before launching into full-scale development.

Planners seem particularly keen to bring new telecommunications technology to the business community. In 1983, French companies will be able to make use of the services of a satellite more or less devoted to business communications when Telecom 1, a satellite being built with PTT backing under the direction of the French space agency, CNES, is launched. In addition to providing business links, Telecom 1 will free France from the expense of leasing channels on Intelsat satellites for telecommunications links with its overseas territories.

The Mitterrand government clearly shares the view of its predecessors that modernization of the network is essential. But where the old and the new policies may part company is in a strategy for widespread introduction of télématique — the uniquely French word for the information systems created by linking computers via telephone lines — into homes. The new government is sceptical of the economics of the Giscardian plan to give every home a télématique terminal. And Jacques Dondoux, the new director of telecommunications, has made a concession to public anxieties about the social impact of télématique by agreeing to set up a users' group to discuss the issues.

The previous plan to install and experimental electronic telephone directory into every home in Ille et Vilaine in Brittany has

thus been modified to give householders the right to refusal. Householders in Velizy, a small town near Paris, are also to be allowed to choose whether to participate in an experiment to monitor the use of Teletel, the French public viewdata system. The results of both these experiments, which began last year, will be fed into a national debate on the new technology.

PTT plans to finance its future investment programme in much the same way as it has in the past — from earnings and money borrowed abroad. As the network grew, the proportion of investment raised from receipts grew from 43 per cent in 1977 to 74 per cent in 1980. The hope is that three quarters will come from cash flow.

Thus the pressure on the public purse should continue to be minimal. But the Mitterrand government, in its eagerness to offer the benefits of new telecommunications technology to everyone that wants it, has already suggested that PTT offer special tariffs to certain groups, for example the elderly. If it sticks to its guns, then PTT will be looking for public money to make up the deficit.

Microcomputers for all

WHILE other countries agonize over the social impact of new information technologies, France is preparing to take the bull by the horns in the form of a new centre set up last October with an annual budget of FF 100 million. The Centre Mondial, as it is known, is the brainchild of Jean-Jacques Servan Schrieber, author of the book *The World Challenge*, who believes that microcomputers can wipe out social inequality by bringing information to all. Last week, the Centre Mondial held its first assembly.

Professor Nicholas Negroponte, professor of computer graphics at Massachusetts Institute of Technology is managing director. He will be supported by a board consisting of 12 French cabinet ministers and a group of French and foreign scientists. Around 50 researchers will be appointed this year and a further 50 by the end of 1983.

The idea, however, is not simply to get computer scientists to design micro-

computers. The public must also be involved in testing new and existing information technologies. Hence the centre will be establishing offices where passers-by can test out various wares. The ultimate aim is to feed public reaction into the design of a powerful microcomputer, costing no more than £100, for personal use.

In the meantime, the centre will study social questions such as the human-computer interface and the value of information technologies to members of different cultures. Two projects have begun. One, to bring microcomputers to a quarter of Marseilles in collaboration with the University of Aix at Luminy, will test the French response to the new technologies. But the other, to train young people from Senegal in the use of microcomputers, will be used to assess the usefulness of the new technologies to those living in developing countries.

National trend in space

THE enthusiasm of the Mitterrand government for science and technology has not been lost on the Centre National d'Etudes Spatiales (CNES), the French national space agency. CNES has been promised 18.7 per cent more money, in real terms, in 1982 than in 1981. The lion's share of the FF 3,000 million budget for this year, which makes CNES the largest national space agency in Europe, comes from the research ministry. But other government ministries which must contribute towards development of services they wish to use have also stepped up their payments. These include the ministry of defence, which wishes to launch satellites on Ariane, and PTT (the telecommunications ministry) which is contributing towards the cost of Telecom 1, a national telecommunications satellite.

For the time being at least, the new government seems keen to support the space policy of the old. Thus, last October it formally approved CNES's involvement in four new projects of the European Space Agency (ESA) and a second national remote sensing satellite, Spot 2. CNES will have no difficulty spending this year's extra money according to Professor Hubert Curien, the centre's president, largely because Spot 1, the first national remote sensing satellite, is now entering the most costly phase of its development. But if the budget continues to increase over the next five years, as promised, how will it be spent? CNES hopes to persuade its own government and those of its partners in ESA to embark on projects that rely less than in the past on the good will of the United States and the Soviet Union for their success.

Since CNES was created 20 years ago this month, it has followed a policy of multilateral and bilateral cooperation that has benefited both national space industries and the space science community. Hence, membership of ESA has given French engineers the opportunity to participate in the development of their brainchild, Ariane, a project that would have been too costly for national development. And the policy of bilateral cooperation with the Soviet Union as well as the United States and individual European countries has given the French space science community perhaps more opportunities than its counterparts in, say, Britain and Germany.

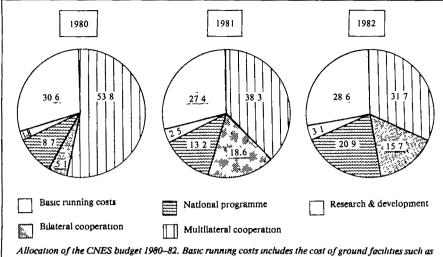

International collaboration, however, has not always run smoothly. CNES still remembers, for example, NASA's decision to withdraw from participation with ESA in the International Solar Polar Mission. Joint projects with the Soviet Union have caused similar frustrations. And the decision of the Soviet space agency to extend its next mission to Venus to include Hally's comet meant that CNES had to abandon plans to send a probe into the atmosphere of Venus.

CNES now wants to shake off the shackles of being the junior partner in collaborations with the two space powers, whilst retaining a strong commitment to Europe on the grounds of necessity. It is following two paths towards its goal. The first involves persuading the French government to support an enlarged national space programme, especially in science. And the second involves persuading the members of ESA to develop an ambitious launcher as a successor to the current series of Arianes.

Hubert Curien — keen to promote ESA as senior partner in bilateral projects

The national space programme centres on the development of applications satellites, five of which will be launched in the next three or four years. These include a telecommunications satellite, Telecom 1, due for launch in July next year; a direct broadcasting satellite, TDF 1, identical to West Germany's "TV-sat"; and two Spot remote sensing satellites for launch in 1984 and 1985. But when these projects come to an end, CNES may well decide that most future research and development in applications, especially telecommunications, should be hived off to national industry which has already developed more expertise in space technology than many of its European counterparts.

Allocation of the CNES budget 1980-82. Basic running costs includes the cost of ground facilities such as the technical centre in Toulouse. The amount spent on multilateral cooperation has decreased as ESA's programme to build Ariane has reached the end of the first development phase. The increase in the proportion spent on bilateral cooperation in 1981 was due to the start of the Venus-Halley mission with the Soviet Union and the Franco-German collaboration on direct broadcasting satellites.

The field could then be open for the first national scientific satellites since 1975. The French space science community, enthused by the possibilities, thrashed out about ten proposals at a meeting last year for wider discussion at the national colloquium on science and technology held in Paris last January.

CNES is studying the feasibility of all the proposals, some of which will eventually be put to ESA. But two, a gamma-ray observatory, Sigma, and a wave altimetry experiment, Poseidon, have been singled out for national development. The reasons for choosing them were their scientific merit and the urgency with which they would need to be developed. The plan is to launch Sigma at the end of 1985 on the first qualification flight of Ariane IV, the latest

Da ili nyet

THE programme to put a French astronaut in space aboard Soyuz-Salyut later this year contributed to CNES's mistrust of bilateral deals when the Soviet space agency refused to release details of the spacecraft for reasons of military secrecy. French engineers then had no option but to guess the specifications for the instruments they are putting on board. In the event, the Soviet space agency allowed French technicians to travel to Moscow for consultation provided that they did not enter the buildings where the spacecraft were being built. But in general, when French engineers ask whether their guesses are correct, the Soviets simply reply "yes" or "no". The result, according to Professor Curien, is "trial and error with rapid convergence". Added to these technical problems is the growing row among French space scientists over the political wisdom of Soviet collaboration. Many are now objecting because of events in Poland and the human rights issue.

Judy Redfearn

version of Ariane to be approved, and to carry the Poseidon experiment on board Spot 2.

CNES now has the task of persuading the French government to find the money for these projects, which could entail almost doubling the space science budget. Financial pressure could be eased, however, if other countries could be persuaded to participate as junior partners. Discussion over collaboration on Sigma has already begun with scientific groups in Italy and Britain.

Thus, with national scientific projects, CNES hopes to regain the power of decision it believes it has lost in many of its international undertakings. Professor Curien would like ESA to follow suit. France had supported moves by Germany at the end of last year to increase ESA's science budget by 20 per cent after 1983. Other members states vetoed the proposition but CNES now hopes that if some of its scientific proposals cannot be afforded within ESA's mandatory science programme, then sufficient member states can be persuaded to participate on a voluntary basis.

Professor Curien believes that ESA too could gain greater control over joint projects with non-European countries if it initiated attractive projects in which, say, US scientists could be invited to participate. His proposal, however, has met with resistance from some members of ESA who fear that US participation could swamp what should still be essentially European projects. The outcome may depend on the findings of a committee of the European Science Foundation.

The strongest evidence of the importance that CNES now attaches to national and European independence in space, however, is to be found in its belief that Europe must build a new generation of launchers that will rival the descendants of the US space shuttle in the 1990s and beyond. At a meeting organized by CNES earlier this year, Yves Sillard, then

director-general, urged representatives of the European space industries to come up with proposals within the next two years. The French idea is to develop an advanced launcher consisting of the first stage of Ariane IV with a powerful cryogenic motor for the second stage. A third stage could be added later. CNES engineers plan to put a proposal along these lines to ESA by early 1984 with the aim of reaching a decision in sufficient time for an operational launcher by 1994.

The French philosophy is to design a flexible system that could launch the future generation of applications and scientific satellites and give Europe independence in new space applications such as material processing. The dilemma is knowing whether Europe will need men in space or whether it should design fully automated systems. CNES engineers are trying to avoid the problem by designing a partly recoverable, automatic system, initially compatible with Ariane IV, that could be converted to manned spaceflight, using the more advanced launcher, when and if the need arises.

Two separate but related projects are under study. The first, Star, a geostationary satellite that would maintain permanent contact between satellites and a ground station by relaying signals between them, may be affordable nationally. The second, Solaris — consisting of one or two Star satellites, an automatic space station in low Earth orbit and an automatic recoverable servicing vehicle - would be costly enough to justify collaboration within ESA. The recoverable vehicle would be of sufficient power to ferry, for example, materials for space processing between earth and the space station. It would also be capable of carrying out routine maintenance and repairs on the space station. Fitted with a suitable boost motor, it could be sent on servicing missions to satellites in geostationary orbit.

The development of both Star and Solaris demand research on space robotics and advanced control systems which CNES and ESA are currently supporting, albeit on a small scale. Ideas for putting men in space centre on developing a suitable recoverable servicing vehicle and space station for the Solaris system and a more powerful launcher. CNES is supporting feasibility studies of a small manned vehicle, Hermes, and a cryogenic motor with up to 100 tonnes of thrust for the second stage of the advanced launcher.

The French government, with its plans for dragging French science and technology to near the top of the international league and with its penchant for national independence through international collaboration, seems set to go ahead with these plans. But the success of CNES's proposals will depend critically on whether other governments, which may prefer to leave the expense of advanced launch systems to NASA, can be persuaded to play ball.

Taking a nuclear power lead

"ONE reactor, one producer, one seller": that is the structure of the French nuclear industry, and according to one observer it is a prime example of how France has managed to mobilize its technical resources towards particular goals. Whether this technocratic centralism will survive a socialist government has yet to be seen, but the nationalization of large sectors of industry, and the grand "mobilization programmes" of the minister for research and technology smack not so much of a change as a clarification of previous government positions.

The reactor is the pressurized water reactor (PWR), built under licence from Westinghouse in the United States; the producer and seller the 5,000-strong company Framatome, now geared up in its pressure vessel and steam generators shops at Le Creusot and Chalon to produce six 1,300-MW reactors a year. Mitterrand did not nationalize Framatome. It was already in effective government control through its sole French customer, Electricité de France (EDF) and its principal collaborator in research, the Commissariat à l'Energie Atomique (CEA).

The main impact on the Framatome programme has been the reduction in the EDF order from a possible nine reactors over the next two years to six, which leaves Framatome with a large surplus capacity and a hunger for export orders. Framatome has sold one reactor a year for export over the past eight years: two to Belgium, both to come into operation this year, two to South Africa (to operate next year), two to Iran (although the orders were cancelled by Khomeni with the plants halfcompleted) and two to Korea. The sale to Korea was a considerable achievement because Korea's previous reactors had been constructed by US companies.

Nucléaire, s'il vous plaît!

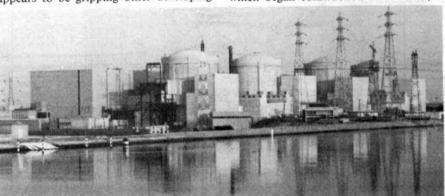

A SLIGHT majority of the French people is in favour of nuclear power, a poll conducted just before the October 1981 energy debate indicated. Some 45 per cent are in favour, compared to 40 per cent against and 15 per cent who don't know, in a sample of over 2,000 people. On the extremes, 16 per cent were "definitely" favourable, and 17 per cent "definitely" unfavourable.

One surprising result which might give the government pause, however, was that 64 per cent were in favour of a referendum on nuclear power — an election promise that was subsequently dropped. Another surprise: nuclear power is more supported on the political left than on the right. Compared with the average 45 per cent in favour, 51 per cent of those who voted communist and 52 per cent of those who voted socialist favour nuclear development.

Framatome has also put in tenders for two reactors for Taiwan and two for Mexico - and if it were not for the world recession would be confident of orders. The dollar rose by nearly 30 per cent against the franc during 1981 (from FF 4.5 to FF 5.8), giving Framatome a distinct price advantage - which is enhanced by the company's ability to spread its overheads over a large national programme. However, Mexico, at least, concerned about its economic situation, is beginning to have doubts about whether it needs the 20 reactors it was planning to build by the year 2000, and the same fear appears to be gripping other developing

Coudray, is that while the Texas reactors are not likely to go critical before 1984 (three to four years late), the first Framatome 1,300-MW reactor — at Paluel — should be connected to the grid early next year. Framatome will thus have taken less than six years to build it, whereas Westinghouse will have taken more than ten years for a similar reactor.

In part, this achievement can be put down to standardization. Framatome has not had to make substantial changes in design in mid-stream to meet changing safety regulations. Apart from the first five reactors, which were fairly variable — Framatome was on its learning curve — there have essentially been only three designs: a group of 16 reactors of 900 MW which began construction in 1974-76; a

Pride and glory reflected - four of France's "production line" PWRs, at Tricastin

states interested in nuclear power. So Framatome may be forced to look to the home market.

In France, Framatome is now building 26 reactors with a total power of 28.6 GW electric, 16 at a nominal 1,300 MW and 10 at 900 MW. Another thirty units, accounting for 21.8 GW, are already in operation. The smaller reactors are effectively the original Westinghouse design, as modified by Framatome; but the 1,300-MW plants are almost completely French, and a new 1,400-MW design, called "N4" and now on offer to EDF, is totally so.

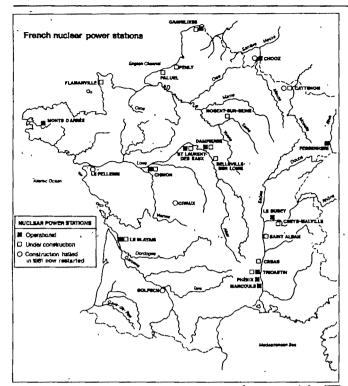

Going it alone

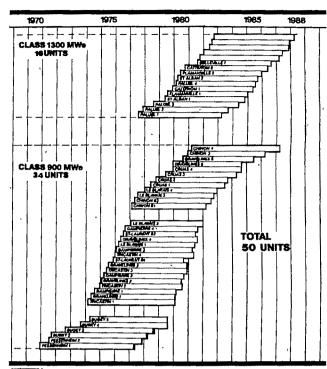

The Westinghouse licence expires this year and then Framatome will be officially on its own - apart from certain research agreements which will continue - but already the sluggishness of the US nuclear programme has given Framatome a commanding lead. According to Framatome's technical director, M. Michel Coudray, the company began work on the 1,300-MW design in 1975. By then Westinghouse had already sold two 1,300-MW systems to a Texas utility, and Framatome believed that it would be able to benefit from Westinghouse experience before putting the final touches to its own 1,300-MW plants. But in the event, construction of the Texas reactors has ground almost to a halt, due to quality control problems on site and concern on the part of the Nuclear Regulatory Commission. The result, said

second group of 12 begun in 1977-81; and the 1,300-MW reactors, begun in 1977 in parallel with the second tranche of 900-MW systems. The result has been that Framatome has been able to place long orders for components, which gives a guarantee of supply, and streamlines production processes. (One danger, however, is that mistakes, once made, are propagated over many systems; see p.301.)

With this powerful production system now established, Framatome would, of course, like a long list of orders; but even under the unbounded nuclear enthusiasm of the previous government, orders came only in occasional handfuls. Furthermore, EDF is now producing 40 per cent of its electricity from nuclear power, and while it aims for 60 per cent nuclear by 1985 (compare Britain's present meagre 11 per cent contribution), there is finally a limit to the proportion of an electric power network that can be driven by nuclear systems. The reason is that national power demand fluctuates by as much as 40 per cent during a working day, and nuclear power stations are not easy to turn on and off: they are said to provide "base-load power". So already, EDF has insisted that Framatome consider the problems set by imposing a ten per cent peak to peak fluctuation on demand.

This so-called "daily load follow and frequency control mode" leads to a number of new technical problems, caused by the high frequency at which the control rods have to be driven in and out (up to

The map shows the sites of the French PWRs, filling many of the suitable sites on France's rivers. The figure on the right illustrates the pace of the PWR construction programme since the early 1970s. The boxes extend from the start of construction to connection to the grid.

1,000 times a day according to some estimates) and by the thermal stress on components as the core heats up and cools.

Nevertheless, Framatome has undertaken an extensive test programme at Cadarache, in conjunction with EDF and the CEA, to discover the behaviour of the reactors under such conditions, and the company believes it is now in a position to make the necessary design changes.

By 1990, French orders may be down to two reactors a year. Outside France, Framatome has sought to sell in many countries — including Britain, whose rejection three years ago of a possible arrangement with Framatome is still a bitter memory in the company. The UK Central Electricity Generating Board was said to be quite enthusiastic about an agreement with France over PWR construction, but the Atomic Energy Authority (AEA) was cool. "Britain could have had an industrial agreement, or a research agreement or both but she decided to go with Big Brother [the United States]", said Coudray recently. "Once again Britain has preferred America to Europe" he said, reflecting a feeling in France that Britain is on all fronts a reluctant European partner.

In the United Kingdom, the chairman of

the UKAEA, Dr Walter Marshall, sees things slightly differently. At the time of the French approach Framatome was stil bound by the terms of the licence with Westinghouse, Marshall points out - sc Britain would have had to "throw ou Westinghouse", with whom negotiations were well advanced, without being able to sign up with Framatome until this year Also Britain would have found it difficul to modify the French design to suit British conditions, for that would have been ar implied criticism of French safety judgements, Marshall argues. Westing house itself, however, was more sanguing about design changes because it could always claim that in the United States it: designs were bound by the rules imposed by the Nuclear Regulatory Commission which might or might not be considered sensible. In France, by contrast, the close knit character of the nuclear establishmen implies that changes are a challenge to the whole system. The Framatome PWR is the world's safest, cheapest and best PWR: sc why change it?

Another, purely commercial reason for rejection of the French deal was that there has been a recognition in Britain that Westinghouse, in the past at least, has been the world's most successful reactor vendor and that on the other hand its credibility as a fuel supplier was severely damaged by President Carter's retrospective legislation on the supplies of enriched fuel. That leads to a natural partnership between Westinghouse and British Nuclear Fuel Limited (BNFL) whereas in a French dea BNFL would have been in competition with the French fuel company, Cogema.

Nevertheless, Britain's nuclear power capability would certainly have grown

My steam generator's better than yours

AKEY problem affecting the running of pressurized water reactors is corrosion of the steam generators — the massive heat exchangers that transfer heat from the primary coolant to boiler water which, as steam, will then be used to drive turbines.

Any boiling kettle makes a lot of noise and bubbling vibration, and the same is true of steam generators. So the tubes which carry primary coolant through the steam generator must be clamped firmly to stop them vibrating and working loose. Tight clamping leads to corrosion at the clamps. Loose clamping, as originally adopted by Framatome, leads to tubes working loose. (Fessenheim 1, the first French PWR, suffers from this.)

So steam generator design is something of a black art, and the engineers at Framatome think they've mastered it and that Westinghouse has not. Britain, for its PWR design, has adopted the Westinghouse "F-type" steam generator. Framatome analysed the basic design of the model F in 1977-8 and was not impressed. The F-type is still just a design—it has never operated anywhere—and the previous model on which it was based had major problems. Westinghouse has solved some of the problems, but nothing like all of them, according to Framatome engineers. "We believe in rugged systems" said one. "The Westinghouse model is more of a watchmaker's approach, with smaller tubing of which there is no experience."

Westinghouse, however, is unperturbed. The company believes Framatome is wrong on water chemistry, and that the French steam generators will corrode within four years. However, EDF, the operator, is proud of the chemical control procedures. "We are keeping our fingers crossed" say Framatome's engineers.

much faster with Framatome, and now France can gloat over the difficulties facing the British nuclear industry - particularly over the design and cost of safety systems. "We are very sorry for the British" said Coudray. "You can increase the cost of a plant by a factor of two if you are not careful with what you do about safety". According to M. Rémy Carle, a director at EDF, the cost of a Framatome 1,300 MW PWR station is now about FF 5,000 per kilowatt (that is, about £600 million in total) - a price that does not include decommissioning, and assumes a reactor on the coast, but includes all other costs. By contrast, at the recent announcement of the completion of the work of the British PWR task force, whose objective was essentially to reduce the cost of safety systems on the PWR, the figures being quoted were more like £1,000 million.

According to Coudray, the problem is that the British have adopted a four-loop, independently pumped emergency core cooling system (for use in the event of the most serious possible emergency, a "loss of coolant accident" or LOCA). Such a system is easier to explain, and "nicer

Coudray of Framatome — unlike the British, not troubled by a suspicious public

intellectually" that the French safety system, says Coudray. The British system takes five minutes to explain whereas the French takes 3-4 hours — but the French system will do everything the British one will do a much lower cost. Britain has probably adopted the "transparent" system for political reasons, thinks Coudray, to satisfy a suspicious public.

How then has France got so far ahead with its nuclear programme? The research programme undertaken by Framatome in the early 1970s, and which was in full swing by 1975, was crucial to success. A licence brought information; but understanding requires research, said Coudray. Research enabled Framatome to move away from and improve on the Westinghouse design. The exact scale of the French research programme has not been revealed, but it matches anything that Westinghouse has done in the United States.

The company does its research under four framework agreements which allow very rapid changes of direction and commitments of money without the need for constant negotiation and renegotiation. Framatome has its own unique programme

All they're cracked up to be?

You couldn't really have a better recommendation. "Now's the time to buy from the French" said Dr Walter Marshall, chairman of the United Kingdom Atomic Energy Authority, recently, when describing the French design for a pressurized water reactor (PWR). Dr Marshall heads the PWR task force which recently tidied up the design for a British PWR, built under licence from the American company Westinghouse. However, the recommendation is somewhat backhanded.

"The French have been caught with their pants down", said Marshall, referring to a series of cracks discovered in the reactor pressure vessel and steam generators of a number of plants three or four years ago. The result is that the manufacturers, Framatome, are now taking every possible precaution to avoid such potentially dangerous flaws, even though their own "pessimistic" calculations had shown the existing cracks to be unimportant.

Marshall says he has every confidence in Framatome's calculations and experiments, and believes that it has done a "very thorough job". French safety authorities will impose a requirement to inspect existing cracks every time a reactor is shut down for servicing (perhaps every 2–3 years), and Marshall—who made a deep study of the problems of cracking in reactor pressure vessels—believes this will be quite sufficient to prevent accidents.

This is despite the fact that some of the cracks, which appear in the black steel under the stainless steel cladding of the primary containment system, are difficult to observe. They are the ones in the shoulders of the inlet nozzles of the pressure vessel, where cool primary circuit water enters to extract heat from the core: it is simply physically difficult to reach them with the usual ultrasonic and eddy current detectors, unless the whole of the core is removed first. But Marshall believes it would be adequate to monitor frequently only the cracks in the hot outlet nozzles, which are accessible, as a kind of statistical sample of crack growth, while inspecting the inlet nozzles less frequently — say every ten years — a policy which Framatome and EDF will probably follow.

Around 25 of Framatome's earliest reactors are affected by the underclad cracking problem — an example of how design continuity can lead to problems if the design or manufacturing process has a hidden fault. But the cracks may prove to be a very minor hitch compared with another problem which became apparent only this January — faults in the "broches".

These are spring clips which grip and support the fuel cans at the top of the core, and some three years ago in Japan it was discovered that they can be subject to embrittlement caused, perhaps, by neutron bombardment. Until January there had been no evidence of this in Framatome reactors, but then a loose part of a broche was found circulating in the primary coolant in one of the Gravelines reactors. Now the loading of the latest Framatome reactor, at Chinon, has been delayed according to some reports to test and inspect or even to change all the broches before the reactor is started.

Framatome staff do not understand yet what caused the Gravelines broche to break, and whether it was a unique or general fault. But if it was the latter, 37 reactors would be affected, so a crash programme on broche design and testing is now under way. The problem is compounded by the fact that the broches on working reactors will be highly irradiated and so very awkward to replace; but if faulty, they will have to be replaced, for broken broches could jam and interfere with the movement of control rods.

at Creusot-Loire, mainly on materials; a "very privileged and active" programme with the CEA (which is, incidentally, a 30 per cent shareholder in Framatome); a quadripartite agreement, under which onethird of the work is done in the United States and two-thirds in France; and a tripartite agreement among the French partners. Corrosion problems in the primary circuit and steam generators, among the main causes of the low availability of the Westinghouse reactors, were studied under the quadripartite agreement; but surprisingly Westinghouse and Framatome then diverged over steam generator design (see page 300).

The principal reason Framatome has been so successful, though, lies in the extra-

ordinarily tight organization of the nuclear industry in France — a legacy of the work of the previous industry minister, André Giraud. After the battle between CEA and EDF over whether the French gas-cooled or American pressurized water reactor should be chosen - a battle in which de Gaulle championed the CEA, which he had himself set up in 1945, and its gas-cooled system, and which was only won by EDF after de Gaulle resigned - Giraud picked up the pieces of the industry and dried the CEA's tears, giving it total control of the fuel cycle and the development of the fast breeder. He thus created the stable, threelegged organization - CEA, Framatome, EDF - which has put French nuclear power in a world-commanding position.

Superphénix — great white hope

THE world's first commercial-scale fastbreeder reactor, Superphénix, should be generating 1,300 MW of electrical power for the French national grid by 1984. But is it, or will its successors be, economic? And will EDF order Superphénix II, which is already being designed?

Superphénix is in fact owned by an international consortium, NERSA, which is 51 per cent French with the rest largely divided between Germany and Italy (which has the larger share). NERSA is the customer of Novatome, a kind of fast-breeder companion to Framatome (which constructs the PWR). Framatome in fact now controls Novatome, which is also held 34 per cent by the CEA.

Superphénix is expensive: estimates vary, but the price is usually put at around twice that of the equivalent PWR. Of course, it is a prototype; it is alone on its site (PWRs are usually built in fours); and PWR construction is well-developed (Framatome is on the fortieth of its series). But there are some fundamental reasons why Superphénix should be more expensive: it has an extra cooling circuit the second sodium circuit; safety systems are more complex, having to deal with the possibility of sodium fires as well as almost instantaneous nuclear shutdown in the case of coolant loss; and the reactor vessel is stainless rather than ordinary black steel.

Superphénix nears completion

In the long run, the fuel cycle costs should be lower because the fast breeder can generate its own plutonium by neutron bombardment of waste uranium from 'enrichment plants and depleted gasgraphite fuel.

This would also give France a degree of security in uranium supply. French-controlled uranium production is expected to peak at around 4,500 tonnes a year by the mid-eighties, but the PWR programme is expected to need around 8,500 tonnes a year by 1990 and 12,300 tonnes a year by the year 2025 (according to CEA figures). So France is in danger of becoming almost as dependent on foreign uranium supplies

as it is at present on foreign supplies of oil. The introduction of fast breeders, the CEA argues, could reduce this demand to as low as 8,000 tonnes a year in 2025 — provided a fast breeder programme were started soon.

There are two arguments for the fast breeder, says the CEA: that at a certain uranium price the fast breeder will become cheaper per kilowatt hour than a PWR, because of the former's breeding capacity; and that it represents an insurance against loss of uranium supplies. "And you expect to have to pay an insurance premium if you want insurance," says Michel Rapin, CEA director for nuclear applications.

The question of what balance should be struck between these two arguments is ultimately a matter for government and the electricity supplier, EDF, but neither shows any desire for haste although, says the CEA, France needs "a significant programme" of fast breeders by the end of the 1980s to make any impact on French uranium needs by the second decade of the next century.

Moreover, the reprocessing and other pieces of fuel-cycle plant necessary for a fast breeder programme are uneconomic unless built very large. So the CEA is looking for two options: first, a French programme of seven or eight fast breeders, the first of which should be ordered in 1986–87 or, perhaps more practical, an international collaboration on fast breeder construction on about the same scale.

Of course it would appeal to France if the international reactor were close to Superphénix II, and the CEA has already been looking for partners. In Britain, UKAEA officials also believe in international collaboration on fast breeder programmes, and are contemplating agreements with either France or the United States. However, France was reported two years ago to be asking a price of £20–25 million for access to Superphénix technology, a price which Britain at the time rejected.

The reprocessing technology, whose efficiency in extracting plutonium is critical to fast breeder operation, is not seen to be much of a problem at the CEA. Already 15 tonnes of fast breeder fuel have been reprocessed through small fast breeder plants at La Hague (now closed) and Marcoule, and 380 of Superphénix's 400 or so fuel assemblies have been made of plutonium extracted through reprocessing. "We have closed the fuel cycle" says Rapin.

Moreover the breeding efficiency was "sufficiently positive". In recent years CEA scientists - 1,000 of whom work on reprocessing technology - have reduced plutonium losses during reprocessing by a factor of five. "But that is not exactly the problem" says Rapin. To get a lot of plutonium bred by a fast breeder, a thick depleted uranium blanket is necessary. But the thicker the blanket, the less the concentration of plutonium produced in the outer layers of the blanket. And a low concentration of plutonium means a high reprocessing cost. So the best balance has to be struck between the reactor breeding ratio and these costs. Costs, yet again, come back to the centre of the fast breeder stage, and there are certainly some in France who look at Superphénix and think of another costly marvel - Concorde.

Nuclear power — how committed?

WHEN François Mitterrand was elected president of France on 10 May 1981, the nuclear establishment was worried. His socialist party, a relatively new and unknown force in French politics, had committed itself to a fairly strong anti-nuclear policy. Paul Quilès, the architect of the socialists' plan, was effectively seeking a halt to the construction of new nuclear power plants. If this plan had been implemented, the monopoly electricity supplier (Electricité de France, EDF) would have had only 39 GW of nuclear electricity available in 1990, compared with the 59 GW planned by the previous government, and EDF's supplier of nuclear steam supply systems — Framatome — would have found itself with (to say the least) an embarrassing overcapacity. With the export market also sluggish, this would probably have meant the collapse of the French nuclear industry.

However, six days after the presidential election, a strange thing happened. Giscard d'Estaing's centre-right government was in its last few days of limbo, before the elections to the National Assembly (parlia-

ment) and the establishment of the new government. Usually, no major decisions or commitments are taken at such times. But Raymond Barre, Giscard's Prime Minister, unexpectedly announced that the reprocessing facility for spent nuclear fuel at Cap de la Hague, near Cherbourg, was to be massively extended - at an estimated cost of FF 20,000 million (£2,000 million) to cope with 1,600 tonnes of fuel a year. Some of this capacity was to honour contracts already signed with Belgium, Germany and Japan; but the rest implied a strong national nuclear programme. The decision could hardly have been taken without the tacit agreement of Mitterrand, who would have to carry the policy through. So what exactly was the new government's position on nuclear power?

Initially, it seemed as if the Quilès policy might be adhered to. One of the Mitterrand government's first acts was to "freeze" construction on five nuclear sites — Chooz, in the Ardennes near the Belgian border, Cattenom, Civaux, Golfech near the Pyrénées and Le Pellerin. Plans for a nuclear plant at Plogoff in Brittany were

shelved, at least temporarily.

But then other notes were sounded. Jean-Pierre Chevènement, the minister of state for science and technology and a powerful figure in the new government, declared himself solidly behind the French nuclear programme, and all but described the small French environmental movement as "anti-scientific".

Discarding the chaff

Speaking cynically, it is as if Mitterrand had used the environmentalist tendency in his socialist party only so far as was necessary to help build the party and gain power. Now it was possible to let such chaff blow away. The environmentalists do feel themselves hard done by. Giscard had not even lent them an ear. Mitterrand had appeared to listen, and then ignored them. Recently there was a rocket attack on Superphénix, the world's first commercialscale fast breeder power station. Nobody has claimed responsibility, but there are fears at EDF that this means that an extreme section of the environmental movement has now gone underground.

Although the Mitterrand government can in no sense be called "green", it is showing itself to be sensitive to arguments for more democratic control of technical choice. Mitterrand is emerging as a social democrat, although he would not dare to use this label within his party.

In the energy sphere, the evidence for the socialist government's liberalism came first with an energy debate in the National Assembly last October. In contrast to the Quilès policy, the energy policy revealed by Prime Minister Pierre Mauroy and the junior minister for energy, Edmond Hervé, was very mild. It was forced through against the Quilès faction on a vote of confidence. Instead of 59 GW nuclear in 1990 there would be 56 GW. Instead of nine new reactor starts in 1982-83, there would be six. The La Hague development would go ahead. The fast breeder was not debated. The frozen reactor construction sites would be reopened, if a local vote approved; if it did not, it would be up to the regional council (a higher elected authority) to decide; if the regional council did not approve, the matter would come before the National Assembly mechanism designed, it seemed, to get a 'yes'' vote at some level or other.

The environmentalist lobby looked on the black side — this was just the old centralist technocracy by another name. But there is another view, which as time passes comes more and more to the fore. The Mitterrand government is fiercely realistic — while at the same time wanting to make historic and lasting changes in the nature of French society. It is not going to compromise either on economic development or on a slow, emphatic shift of power away from the Paris-based élite, towards the regions, towards the small enterprises rather than the giant conglomerates.

Realism leads the government to under-

Media plug in here

JUST to the side of the Electricité de France (EDF) edifice in Paris is an unobtrusive set of doors. In the case of a major nuclear accident at one of the EDF power stations it is through this door that most of the world's (official) information about it will come.

For behind this door is a FF 4-million (£400,000) communications suite, the brain-child and pride of EDF's chief public relations officer, Mme Marie-Claude Vigna. Mme Vigna began to plan the suite after a French power black-out in 1979 had led to a great press of journalists in a tiny room in EDF headquarters, all attempting to use five telephones at once. If it was like that for a mere power breakdown, what about a "Three Mile Island", Mme Vigna reasoned?

The consequence is that EDF now has probably the most sophisticated "press office" in France. At street level, television vans can simply plug in to a series of channels giving television output from the suite above. Within the suite, sound-insulated rooms take tapes direct from the major wire services such as

Agence France Presse and Reuters, so that journalists — and EDF staff — can monitor media output by the minute. There are of course more than five telephones; a television studio, executive briefing room; and literally every known form of video recording and playback equipment. And officials being interviewed can be relayed information over private monitor screens which are within their vision but not that of the journalists interviewing them (see photograph below).

Outside Paris, hundreds of EDF officials throughout France will be kept in touch by a private videotext signal, sent through the French ANTIOPE system.

A French prefect (regional head man) who was responsible for the region around the Dampierre nuclear power station recently sent out a notice to his constituents telling them what to do in case of a nuclear accident. Don't panic, he said. Keep your children indoors. Don't eat apples from the garden. And, mysteriously, don't telephone. Well, there'd be no need to with what EDF has in Paris, would there!

Energy minister Edmond Hervé confronts the press in EDF's media room

stand that a country 70 per cent dependent on foreign fuel, whose healthy non-oil trade balance is wrecked by the cost of oil imports (99 per cent of oil is imported), must attempt to internalize the costs of energy production. Nuclear electricity is part of the solution. The government is also realistic enough to know that the wholesale destruction of the nuclear industry would be immensely demoralizing to French people - who, while being as suspicious of nuclear power as the next nation, see its success as one of the great symbols of French strength. France has been overrun by a foreign power three times since the Revolution, and no Frenchman is going to let it happen again - either militarily or economically.

Handling the public

On the other side of the equation, the small group of men at the head of EDF, the CEA and Framatome, who effectively control the nuclear development of France, are gradually being forced to pay serious attention to the general concerns of the public and the particular demands of the regions

where nuclear facilities are being sited.

For example, when the government says it will "reinforce the independence" of the Conseil Supérieure de la Surété Nucléaire (the senior nuclear safety council) and "modify its composition", it means that it really will attempt to detach the safety council from its tutelage to the nuclear establishment. The proposal to create a "safety director" under the control of EDF may be looked at a little askance, as may guarantees of the independence of the Institut de Protection et de Surété Nucleaire, the technical safety assessment body which exists under and has constant exchange of staff with the Commissariat à l'Energie Atomique; but the establishment of local information commissions on each nuclear site could be taken more seriously.

These commissions are proving slow to set up (so far there is one at La Hague and another at Nogent-sur-Seine) but, according to commitments made by the government in the energy debate, they will be pluralist, "contradictoire" (in other words allowing serious debate and close questioning), independent and permanent.

Hard bargaining at Golfech

The apparently anodyne decision to subject the five frozen construction sites to a hierarchy of democratic assessments, from local to national level, until at some stage somebody said "yes", has also proved a thorn in the EDF flesh. The votes went in favour of continuing construction at Chooz, Cattenom and Civaux. But at Golfech, near the border with Spain, and Le Pellerin, there were marginal local votes against. So the question went to a higher level — the regional council. The Le Pellerin council voted for the reactor. But Golfech, while eventually agreeing, drew blood from EDF in the process.

The "blood" took the form of a contract with EDF — the first ever such binding arrangement between EDF and a region — which guarantees the locality 40 per cent of the jobs that will eventually be created at

Michel Rapin of CEA says the nuclear programme is stronger under Mitterrand

the power station, a large fraction of the construction work and EDF support for amenity development. EDF is currently seeking sites for five reactors at 1,300 MV and one at 900 MW — the programme agreed at the National Assembly for 1982–83 — and the Golfech deal may prove to be an awkward model. EDF, however, argues that it has always tried to place jobs and contracts around the region of a nuclear site. The real difficulty, says EDF, will be to find 40 per cent of its nuclear engineers in the Midi-Pyrénées.

The latest twist in the tail is literally there—at the tail end of the nuclear fuel cycle. Waste disposal has been neglected in France (although the Marcoule process for the vitrification of highly active waste has been adopted by Britain). Edmond Hervé, minister for energy, has asked the CEA to provide, within a few weeks, an outline plan for the management of nuclear wastes. No such plan exists at present, it seems. Within 18 months, two or three disposal sites must be selected, promising a new political problem for nuclear power.

Some in the nuclear establishment, however, are quite sanguine about the developments. Michel Rapin, director for nuclear applications at the commissariat, believes the new political approach will actually strengthen the nuclear programme, by providing a degree of democratic assessment. Once there has been a vote, who can disagree? All very well, while the votes are "yes"...

Trebling renewable energy by 1990

ONE of the most surprising but rational moves made by the Mitterrand government in the energy field has been its appointment of Michel Rolant, a union activist in his late 40s, as the head of a completely revamped organization to promote renewable energies in France.

Rolant was an agricultural worker who took a strong interest in labour relations, and early on became general secretary of the federation of agricultural workers, a branch of the liberal union, CFDT. But his attention shifted to industry and employment, and he established a reputation, among the pro-nuclear lobby, of being totally anti-nuclear. Certainly, as CFDT's number two, Rolant moulded the union to form effectively the only organized opposition to the nuclear establishment — a position which it will retain despite Rolant's departure.

Electricité de France is turning a rather jaundiced eye on Rolant's appointment — the cosy club of grandes écoles men at the top of the ministries and the great industries is being jostled these days by one or two workers with some peculiar ideas — but for the government the move is really a master-stroke (and, by the way, one long advocated by CFDT). For, from the nuclear point of view, one of the principal irritants has been mollified: he

to be determined. The CFDT recommends a balanced regional and central organization, with 22 regional branches each with perhaps 50–100 staff, and a 600–700 strong national body. (By comparison, COMES and AEE presently have about 500 staff mostly in Paris). The new body should also be capable of doing research on its own behalf, together with the major research organizations.

Moreover if capital loans could be arranged on the kind of terms on which they are offered to Third World nuclear purchasers — terms such as 8 per cent interest to begin five years after completion of a reactor as were offered to Korea, for example — then wonders could be worked, say the enthusiasts.

In fact COMES announced an objective at the end of last year: to treble the funds devoted to solar energy between 1981 and 1985. The most promising areas for development were the production of petrol and methane from biomass, particularly wood waste of which France has a particularly good supply. But Rolant will want to see all alternatives, including energy saving, in perspective, and perhaps COMES's priorities will not be his. The government is certainly committed in principle to a trebling of funds for renewable energy projects, although the allocation of the

Consumpti	ion of prin	ary energy:	evolution an	d objectives	*
	1970	1974	1980	1981	Plan 1990
Coal	38.1	31.6	34.0	33.5	35-40
Petrol	87.5	113.2	102.1	93.0	70-75
Gas	9.3	16.0	23.6	24.6	31-40
Hydroelectrics	12.4	12.5	16.0	15.0	14-15
New energies	2.0	2.1	3.2	3.4	10-14
Nuclear	1.2	3.1	12.9	19.5	60-66
Total	150.5	178.5	191.8	189	232
Proportion from indigenous sources (%)	65.6	75.0	71.0	68.0	45-50

^{*}Values are in million tonnes of oil equivalent

is now part of the government club and must be expected to obey the rules. And from the alternative energy point of view, here is a man who is a passionate and serious advocate of such forms of energy who must now turn his dreams into reality. If they work, well, that means more energy for France.

In fact the government's energy plans for the next decade are extraordinarily ambitious both in respect of their nuclear component and their renewables (see table). The energy supply from renewables — such as solar power and biomass — is expected at least to treble by 1990 compared with 1981, and M. Rolant will be presiding over that growth. Rolant will have available to him COMES, the commission for solar energy, and the AEE, the agency for energy saving, which will be formed into a new organization whose exact definition and scale have yet

cash will not be known until mid-1982.

No doubt Rolant will have considerable influence on this, and perhaps his agricultural background will influence him (his colleagues at CFDT deny it); but it has been clear for some time that in renewables France is concentrating on the conversion of biomass. Of the 10-14 million tonnes of oil equivalent expected from renewables in 1990, half will come directly from the use of wood, and a further 2 million tonnes of oil equivalent from wastes. Surprisingly, however, of FF 35.2 million (£3.5million) research ministry funds available for renewables research in 1981, only FF 0.2 million (£20,000) went to support biomass research. The largest sum (around half) went to coal. COMES spent FF 50 million (£5 million) on biomass development in 1981, but only a small fraction of that went on basic research. This may change.

Demon nuclei— spurious excitement?

GAMERA A COMPLEX

CIR RAPY COMPLEX

Description of t:

Chambe a compression of the complex
from Frank Close

CAN quarks, the hypothetical ultimate constituents of all nuclear matter, cluster together and form 'demon' nuclei - an exotic form of nuclear matter in which individual protons and neutrons cannot be discerned? The existence of such matter has been recognized as a possibility for some time, but now great excitement has been caused by a claim that 'demon' nuclei may actually have been detected. Early this year S. Fredriksson and M. Jandl of the Royal Institute of Technology in Stockholm (Phys. Rev. Lett. 48, 14; 1982) predicted, from a new theoretical approach, that demon deuterons might have been responsible for anomalies seen both in cosmic experiments and in recent experiments at the Lawrence Berkley Laboratory. However, an even more recent paper suggests that the excitement may be premature. H. J. Lipkin of the Weizmann Institute (WIS Report 82/2, January; 1982) raises powerful theoretical objections to the existence of demon deuterons and shows that whatever is responsible for the experimental anomalies, it cannot be demon nuclei.

The ways in which quarks cluster together to build up nuclei can be thought of as similar to the ways that electric charges cluster together to build atoms and molecules. In the latter case, electromagnetic attraction between opposite charges causes electrons to encircle the atomic nucleus to build up atoms whose total electrical charge vanishes. Neighbouring atoms are held together by three varieties of forces, each of which has its origin in the fundamental electromagnetic force. Neighbouring atoms with an excess or deficiency of an electron can be directly attracted (ionic force); electrons can be shared among atoms (covalent force); or there can be an asymmetric distribution of charge within the overall neutral pattern (van der Waals' forces).

Quarks carry a property called colour which is similar to electrical charge except that instead of there being just one variety of positive charge there are three varieties (red, yellow and blue) of positive or negative colour. Unlike colours attract just as unlike charges do. Quarks carry positive

colours and their antimatter equivalent, anti-quarks, carry the negative or complimentary 'anticolours'. Quarks and antiquarks will thus be mutually attracted and form the variety of matter known as mesons, of which the pion is the most familiar example. However, because of the threefold nature of the colour charge there are possibilities for quark clusterings which do not have a direct analogue in electromagnetism.

For example, two 'red' quarks will repel one another, but if a red and yellow one are nearby they will be mutually attracted. If a third quark carrying a blue colour is near to this pair, then the red and yellow, yellow and blue, and red and blue will all mutually attract one another and can form a stable system known as a baryon, of which the neutron and proton are the lightest examples. If a fourth quark comes near to this system it will be repelled by the red-, yellow- or blue-coloured quarks depending on which colour it is itself carrying. Three quark clusters are thus very stable and this is the source of the baryon's existence.

In the cluster of red, yellow and blue quarks that forms the baryon, the total colour has cancelled out leaving no net colour: just as the electrically neutral atom results from electromagnetic forces. In turn, the forces that cluster adjacent neutrons and protons to one another to form nuclei are the colour analogues of the covalent or van der Waals' forces of electromagnetism. An important difference between colour forces and electromagnetic forces is that colour ions appear to be forbidden to exist as free entities in nature. Thus individual coloured quarks or pairs of quarks which carry net colour have no free existence, although this need not prevent the existence of colour ions within densely packed clusters - so long as the total colour of the whole cluster vanishes. Indeed, within the proton there exist two quarks with net colour which are attracted to the third quark which itself

carries colour; in this sense the proton is built of a di-quark coloured ion and a quark coloured ion. Could there, then, be ionic forces between di-quarks within nuclear matter? The simplest example would be in a cluster of six quarks of which the most familiar example is the deuteron; three quarks form an uncoloured cluster known as the proton and the remaining three form an uncoloured cluster, the neutron. The neutron and proton then attract by the residual colour forces, analogous to covalent forces (pion exchange) or to van der Waals' forces (about which there is much theoretical discussion but not total consensus vet). However, there is also the possibility that this total of six quarks, instead of forming two uncoloured clusters of three, might form three colour ions of two! Thus the deuteron, which is two sets of 'tri-quarks', could have a demon brother which is a set of three di-quarks. The di-quarks carry colour and will be strongly attracted to one another, in a manner analogous to ionic forces. They will be bound very tightly in a cluster of six quarks, in contrast to clustering into groups of three where the residual force would be expected to be weaker. Thus, it seems in principle possible that a stable cluster of three di-quarks exists in nature, perhaps lighter and more stable than the familiar deuteron.

This idea is at the root of the paper by Fredriksson and Jandl. The authors predict that their demon deuteron will be light enough to be almost stable and might be responsible for the anomalous nuclear interactions that have been seen in cosmic experiments (the Judeck effect) and in recent experiments at the Lawrence Berkley Laboratory (E.M. Friedlander et al. Phys. Rev. Lett. 45, 1084; 1980). When a high-energy nucleus collides with an emulsion target, it was discovered that about six per cent of the fragments created in the collisions travelled only very short distances, much less than normal, suggesting that they were somehow anomalous with very high reaction cross-sections, long lifetimes and stable against strong decays. Fredriksson and Jandl suggest that the large interaction cross-section arises

Frank Close is Principal Scientific Officer in the Rutherford Appleton Laboratory, Didcot, Oxfordshire OX11 0QX. because 'demon nuclei' are produced.

Even more recently, important difficulties with this suggestion have been raised by H.J. Lipkin of the Weizmann Institute. Crucial in creating a demon deuteron from three di-quarks is the role of the Pauli principle. Having all three di-quarks in s orbitals violates the Pauli principle and so the authors suggest each di-quark is in a p orbital, the three of them coupling to a total L = 0 state with negative parity.

Lipkin points out that as there are only two independent orbital angular moments in a three-body system, then the $J^p = 0$ -object made from three $J^p = 0$ di-quarks cannot exist. The so-called demon state is a spurious state of centre-of-mass motion in which the centre-of-mass of the three diquarks is oscillating in a p-wave. When this

spurious excitation is removed by putting the centre-of-mass in an S-state then one obtains an allowed state with total angular momentum of one. This isoscalar $J^p=1^+$ has the same quantum numbers as the deuteron, might very well be mixed into the deuteron's wave function and be detectable in measurements of the deuteron's form factors. However it would not be expected to occur as a separate metastable state.

Thus the observation of anomalous nuclear processes on the one hand and the possible occurrence of new multi-quark configurations in nuclear matter on the other remain, for the moment, unconnected. If demon nuclei do exist it seems that they do not occur in the way that the Swedish group claim.

noted the resemblance of many features of the skull and skeleton of the thecodontian Chasmatosaurus (Proterosuchus) to those of rhynchosaurs. Carroll^{4,5} developed these ideas further and demonstrated close similarities between Heleosaurus, a late Permian eosuchian, and the early Triassic thecodontian Euparkeria. Although clearly similar to Youngina, Heleosaurus had a dentition very like that of Euparkeria and it may have been capable of an upright posture, an advanced feature of many archosaurs. Gow⁶ redescribed Youngina, and also suggested that it was close to the ancestry of archosaurs.

New information on the affinities of rhynchosaurs and sphenodontids is also damaging to the integrity of Romer's Lepidosauria for it is believed that these two groups are particularly closely related. Carroll⁷ redescribed Noteosuchus, a partial skeleton from the early Triassic of South Africa, and interpreted it as the oldest known rhynchosaur. Its ankle structure is similar to that of Chasmatosaurus (Proterosuchus). Carroll stressed that there is no evidence for a close relationship between rhynchosaurs and sphenodontids and that supposed shared characters are either primitive features of all diapsids, or they have been wrongly interpreted. For example, the living Sphenodon has acrodont teeth (fused to the summit of the jaw bone), while rhynchosaurs had deeply rooted teeth. Sphenodon has a row of teeth on two

The Diapsida: revolution in reptile relationships

from Michael J. Benton

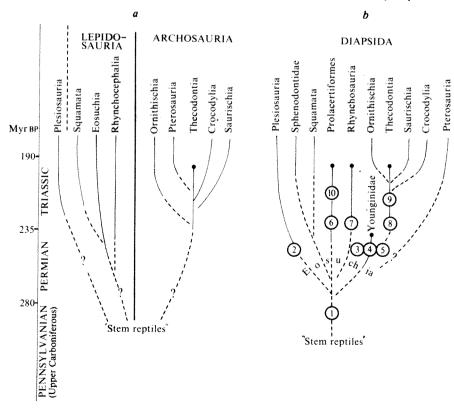

DISCOVERIES of new fossils and reinterpretation of existing data suggest the need for a major change in the traditional view of the relationships and ancestry of the lizards, snakes, crocodiles, dinosaurs and many extinct groups of reptiles. In standard textbooks (for example, Romer's Vertebrate Paleontology), the reptiles are divided into subclasses according to the number of openings behind the eye sockets. Those with two openings, the Diapsida, are further divided into two groups, the Lepidosauria (including lizards, snakes, sphenodontids, rhynchosaurs and eosuchians) and the Archosauria (including the thecodontians, crocodiles, dinosaurs and pterosaurs), that are thought to have diverged from separate ancestors as early as the Upper Carboniferous (Pennsylvanian; see Fig. 1a). The new view (summarized in Fig. 1b) is that all diapsids have a common ancestry and that their classification will have to be completely revised.

Romer¹ considered that lepidosaur groups, including the lizards, snakes, sphenodontids and rhynchosaurs (medium-sized 'beaked' and probably herbivorous reptiles of the Triassic), all derived from the eosuchians, a mixed group of primitive forms, of which Youngina from the late Permian of South Africa is usually regarded as typical. In contrast, archosaur groups, including the crocodiles, dinosaurs and pterosaurs, were considered to be derived from thecodon-

tians, such as the early Triassic Chasmatosaurus (Proterosuchus).

More recent results now suggest that both lepidosaurs and archosaurs had common ancestors among the eosuchians^{2,3}. Cruickshank³ particularly

The similarities between Claudiosaurus, supposedly the earliest plesiosaur, and Thadeosaurus, a contemporary eosuchian from Madagascar, suggest a close relationship. After Carroll¹⁴

separate bones of the palate (the maxilla and the palatine), while the multiple rows of teeth in rhynchosaurs are all on the maxilla. Sphenodon appears to show more affinity with ancestral lizards.

New evidence also suggests that the Pterosauria should be removed from the Archosauria and recognized as a distinct group. As early as the late Triassic, pterosaurs from Italy, described by Wild8, had all the special adaptations of the group for flight and had diversified into two quite different stocks. Wild suggested that pterosaurs originated directly from the eosuchians in the early Triassic since their anatomy suggests that they derived from small running insectivorous forms. The thecodontians of the Triassic were generally too large or otherwise unsuitable as ancestors, and there would probably have been insufficient time for a radiation from them to have occurred.

We can now discern four separate lineages of diapsid reptiles that radiated from the Eosuchia in the late Permian: pterosaurs, thecodontians, rhynchosaurs, and a group made up of lizards, snakes and perhaps sphenodontids. But how do we define the Eosuchia?

Romer¹ included a broad group of Younginiformes, the Prolacertiformes (centred on Prolacerta, an advanced form from the early Triassic of South Africa, that shows some parallel features to lizards) as well as some later aquatic forms. Evans⁹ noted that the Eosuchia have no diagnostic advanced characters and can only be defined by the absence of features typical of other groups. Thus, she broadened the Eosuchia to include all diapsid reptiles except the archosaurs, the lizards and snakes. Further work may enable us to extract some of the motley collection of reptile families from the eosuchian rag-bag when we understand more about the diapsid radiations in the Permian and Triassic.

The confusion over the definition and limits of the Eosuchia makes it difficult to decide whether the Eosuchia had a

common ancestor, but an apparantly suitable form exists. Petrolacosaurus from the late Pennsylvanian (260 million years ago) of Kansas has been redescribed recently on the basis of much new material 10. It was clearly a diapsid, but certain features also indicate its ancestry among the 'stem reptiles'. Chatterjee11 has included Petrolacosaurus in the Prolacertiformes, together with several Permian and Triassic reptiles. He regards the enlarged prolacertiform group as a lineage evolving separately from other eosuchians. Wild12 has independently come to a similar conclusion on the basis of a re-study of the curious long-necked Tanystropheus from the middle Triassic

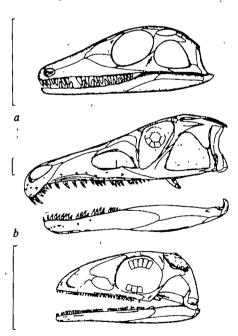

Fig. 3 Side views of the skulls of Youngina (a), Chasmatosaurus (Proterosuchus) (b) and Claudiosaurus (c), an eosuchian, a thecodontian and what may be the earliest plesiosaur respectively. These early representatives of the groups show considerable similarity. Scale bars are 2 cm

After Carroll¹⁴ and Cruickshank³.

period of Switzerland.

One recent study adds a further dimension to the diapsid reptiles by suggesting that the aquatic plesiosaurs, previously of uncertain affinities, derived from the Eosuchia. Carroll¹³ described two reptiles from the late Permian of Madagascar: Thadeosaurus, a younginid eosuchian, and Claudiosaurus, which he interprets as the first plesiosaur (see Figs 2,3). Claudiosaurus resembles younginids in its general anatomy, but it lacks the lower temporal bar and has a closed palate - typical plesiosaur features. Although it does not show all of the particular adaptations for aquatic locomotion that plesiosaurs had (paddle-like limbs, streamlined body, strong tail), certain features suggest that it was a swimmer (poorly ossified wrist and ankle, proportions of the limbs, small skull, long neck). The ancestry of plesiosaurs has been problematical, but Carroll makes a strong case for their derivation directly from diapsid reptiles during the Permian.

There now seems to be little evidence for the separate status of the Lepidosauria and the Archosauria, and it appears that all diapsid reptiles can be derived from Petrolacosaurus. Thus, we may re-instate the Subclass Diapsida, established by Osborn¹⁴ in 1903. This group will now contain a large number of forms, many of them poorly known, and future work must concentrate on sorting out their relationships.

Two bar mitzvahs for tubulin

from Chandler Fulton

Among the thirteen years since tubulin was named1, the past year has been particularly exciting*. Complete sequences have been reported for both α -tubulin and β -tubulin subunits, the heterodimer of which constitutes tubulin, and it is now clear that cells contain multiple tubulins encoded in multiple genes.

Tubulin is the major building block of microtubules. All eukaryotes have microtubules, so the first eukaryote

*This report is inspired by two meetings which might be said to have celebrated tubulin's reaching, in human terms, the age of responsibility: a joint symposium of the Embryology and Physiology courses at the Marine Biological Laboratory on "Organization and Expression of the Genes for Tubulin", organized by R. Raff and J. Rosenbaum and held at Woods Hole on 17 July 1981, and a European Molecular Biology Organization Workshop, "Microtubules in Microorganisms", organized by P. Cappuccinelli and held at Porto Conte, Sardinia, on 8-12 September 1981.

presumably had tubulin, probably already utilized for the conserved functions of mitosis and flagellar movement. Yet the origin of tubulin is lost in antiquity (about 3×109 BC). Margulis2 has provocatively proposed that microtubular structures arose through integration of an endosymbiotic spirochete into a protoeukaryote, but there is only tenuous evidence to support this view.

Three groups have reported the complete sequencing of tubulin subunits from brain, both by direct analysis of pig brain tubulin subunits3,4 and by sequencing of

MAXIM'S SELF-ACTING FIRE-**EXTINGUISHERS**

However certain it is that fires in theatres will never be completely suppressed, we may still hope by energetic measures and systematic arrangements to lessen both their number and their danger.

The stage is undoubtedly the most dangerous point, from the very nature of the materials composing it. M. Maxim's proposes to institute such a preventive system that, as soon as a fire begins to show itself at any given point of the stage, the accident will itself produce automatically and instantaneously a series of mechanical movements sufficient to flood the threatened part with water, and arrest the progress of the fire.

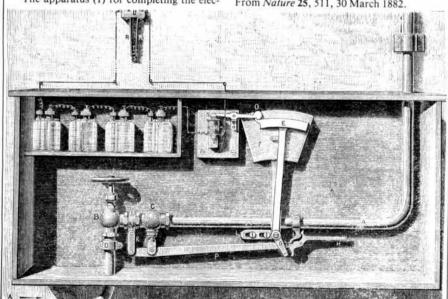

The self-acting *Electric System* he proposes is composed of three distinct parts: (1) an apparatus which completes the electric circuit, under the action of the raising of temperature caused by the fire; (2) a self-acting supplycock, to send water into the system of pipes from the main pipe in the street; (3) an arrangement for opening the discharge-pipes upon any part which is in danger.

The apparatus (1) for completing the elec-

tric circuit is extremely simple. It is composed (Fig. I) of two metallic plates, R. R. forming springs, and separated by a small piece of fusible metal, s, which is isolated from the plates by paper, or any other isolating body. The heat caused by the fire melts the metal, and the plates coming into contact, the electric acts upon the automatic supply-cock. This self-acting supply-cock (Fig. I) is composed of an electro-magnet, M. which, under the action of the current, becomes active, and attracts the arm N, thus setting free the lever, E. The weight, F, then turns from right to left, and, after describing the quarter of a circle, falls upon the lever, H, whilst the part, G, removes a check which has kept the lever, P. in position. Under the action of the weight, F, and by means of the lever, P, which has its fulcrum in the point, J, the supply-cock, c, is turned, and the water rushes into the pipe, A, to be discharged above. The cock at B, which is worked by hand, serves to stop the supply when the fire is extinguished.

The water pouring upwards into the pipes ought to be discharged at the point where the fire appears. Ordinary perforated pipes may be used, and the system of pipes may be disposed around the stage.

From Nature 25, 511, 30 March 1882

cDNA clones to chick brain tubulin mRNA5 and rat brain α-tubulin mRNA6. One immediate consequence is that the molecular weight of both subunits is reduced from the widely quoted 55,000 to 50,000 (450-451 and 445 amino acid residues for α - and β -tubulin respectively). The complete sequences confirm earlier insight that the two subunits share considerable homology3-5. They also support the view that tubulin is among the most conserved of proteins; in 270 million years of separate evolution leading to chickens and pigs, only about 7 of the 855 sequenced residues have been altered. The available information suggests that the subunits diverged from a common. unknown ancestor, and since then their evolution has been held in check, perhaps by functional constraints on the protein. Preliminary evidence based on peptide mapping suggests that protistan tubulins have a-subunits quite different from vertebrate tubulins7. It seems probable that the sequencing of additional tubulin subunits will shed light not only on the structure and function of tubulin but also on the evolution of eukaryotes.

The amino acid sequences and molecular cloning experiments both support the conclusion that many eukaryotes contain and express multiple tubulin genes to produce tubulins that differ slightly in primary structure, an hypothesis that seemed improbable to most when it was proposed six years ago. The protein sequences indicate at least four different α-subunits and two different β-subunits in pig brain tubulin3,4. There are at least two α - and two β -tubulin genes in Chlamydomonas8.9, four of each in Drosophila and chickens, and more than ten in sea urchins, rats and humans10. In Drosophila and in chickens, the multiple tubulin genes are dispersed in the genome (see, for example, ref. 11). All four a-tubulin genes are expressed in Drosophila12, and E.Y. Lai and I have found that at least two β-tubulin genes are expressed during the differentiation of Naegleria amoebae to flagellates. Although the coding regions of tubulin genes are sufficiently conserved for complementarity to be detected among diverse eukaryotes, from yeast to humans5, the flanking regions are divergent even within a single organism (see, for example, ref. 12). The existence of multiple tubulins and tubulin genes requires revision of many of our ideas about tubulin, as well as re-interpretation of old experiments, especially those that measured tubulin pools and synthesis as if tubulin were a homogeneous protein. It also raises questions about the role of multiple tubulins, in particular whether the different tubulins are used selectively in building microtubular organelles. Actin too has been found to be a family of genes and proteins13, which raises similar issues for this protein.

Instructive tubulin mutants are beginning to appear. A testis-specific

β-tubulin mutation has been described in Drosophila¹⁴, which provides evidence that there is more than one functional β -tubulin in this organism. Oakley and Morris¹⁵ have carried out ingenious work on benomylresistant mutants of Aspergillus. A class of these mutants was shown to contain mutations of a β-tubulin structural gene (benA). Some benA mutations alter the isoelectric point of β -tubulin, and these always alter the mobility of two β -tubulin isoforms; thus both isoforms are products of the benA gene. Revertants of a benA mutation were used to isolate a mutation in an α-tubulin gene. A temperature-sensitive benA mutation, with hyperstable microtubules, was used to show that, as Inoué has long argued, microtubule depolymerization is involved in chromosome movement.

The most-studied tubulins have been isolated from vertebrate brains, which are rich in the protein, by cycles of assembly into microtubules and disassembly, but until recently attempts to isolate tubulin from the cytoplasm of protists have been unsuccessful. The systematic isolation of polymerizable tubulin from Physarum amoebae16 and from yeast17 should encourage future attempts and provide opportunities for much-needed comparative studies. Although many properties of tubulin and microtubules, from antigenic determinants to ultrastructure. have been conserved during the evolution of eukaryotes, others seem to vary. For example, whereas colchicine inhibits the assembly of microtubules in diverse eukaryotes, it has little effect on the polymerization of tubulin in many protists. In some of these protists polymerization of tubulin is quite sensitive to benomyl^{16,17}. Although we continue to learn from the exhaustive studies of brain tubulin, novel studies of other tubulins are likely to change our perspective.

The cylindrical walls of microtubules usually contain 13 protofilaments (strings of tubulin), but many exceptions have been reported. Kilmartin found that when

yeast tubulin is polymerized in vitro, in the first assembly there are 12 protofilaments. whereas there are 13 in the second cycle¹⁷. In Caenorhabditis, Chalfie¹⁸ found that although most of the neuronal microtubules have only 11 protofilaments, six touch-receptor cells have microtubules containing 15 protofilaments. Experiments using mutants, colchicine and benomvl indicate that these 15-protofilament microtubules are important for sensory transduction. Proteins associated with microtubules, of which many are known, may determine the number of protofilaments, but we have little understanding of this process. The temporal and spatial orchestration of the intracellular assembly of tubulin into precise arrays of microtubules remains even more mysterious, although elegant descriptive studies of these arrays are beginning to address the issue (for examples, see ref. 19).

In the few years that tubulin has been studied, we have just become acquainted with the possibilities explored during the evolution of cells that utilize this conserved structural protein in cell shape and motility. Much has been learned, but how long will it take us to understand the important features of a crucial eukaryotic protein that has been experimented with for billions of years, among countless billions of organisms?

Was Precambrian seawater different?

from Peter J. Smith

MINERALOGICALLY: dolomite is a simple carbonate of calcium and magnesium. As far as its genesis is concerned, however, it is rather more of a puzzle. Although common in Precambrian rocks, dolomite is apparently no longer being laid down, except in a few marginal environments such as supralittoral zones and ephemeral lakes, even though seawater is supersaturated with it and, on thermodynamic grounds, it should be precipitated in preference to calcite or aragonite (forms of calcium carbonate). Moreover, when it has formed in recent (that is, Phanerozoic) times, it has usually been of the replacement type, which means that it began as calcite or aragonite and later had part of its calcium replaced by magnesium. The geological consensus is that the amount of primary dolomite precipitated directly from seawater during the Phanerozoic has been insignificant compared with the quantity of replacement dolomite generated; and observation shows that, over the same time span, the dominant primary precipitate from seawater has been calcium carbonate (limestone).

This modern preference for limestone has led many, if not most, sedimentologists to suppose that the same bias has always held. The preponderance of dolomite rock (dolostone) over limestone during the Precambrian is then readily explained in replacement terms; limestone has always been the preferential primary product but, being older, the Precambrian representatives have had longer to make contact with magnesium-rich, dolomitizing fluids. There is, however, at least one other possibility — that dolomite was itself the principal carbonate precipitate during the Precambrian because Precambrian

Phanerozoic successor. In that case, Precambrian dolomites (chiefly primary) and Phanerozoic dolomites (chiefly replacement) should be different in terms of their textures, fabrics and isotopic ratios.

That they can indeed be different has now been demonstrated by Tucker

seawater was chemically different from its

now been demonstrated by Tucker (Geology 10, 7; 1982). The Beck Spring Dolomite, which now outcrops in eastern California, is thought to have been laid down 1,200-900 million years ago in various environments ranging from subtidal shoals through lagoons to tidal flats. To Tucker, however, its most conspicuous feature, which it shares with many other Precambrian dolostones, is the extent to which its sedimentary structures have managed to preserve their detail on both broad and microscopic scales. There is no clear evidence of the destruction of original texture and fabric, nor is there any sign of subsequently imposed replacement fabric. Indeed, if other types of analysis had not shown the carbonate to be dolomite of Precambrian age, the Beck Spring Dolomite could well have been taken for an undolomitized Phanerozoic limestone. This is not to say that there have been no changes at all, for there is some evidence of neomorphism. But neomorphism does not necessarily mean mineral change; it could simply have involved wet recrystallization of dolomite.

On the basis of petrographical examination, then, the simplest interpretation is that the dolomite is primary and not a calcium carbonate replacement — a view that receives more than adequate support from isotopic data. Using a scalpel and a dentist's drill, Tucker went on to extract from the Beck Spring Dolomite samples of the various components (micrite, pisolites, fibrous dolomite, internal sediment and so on), which were

then subjected to carbon and oxygen isotope ratio measurements using standard procedures. The results were, of course, numerical in detail, but the general picture is easily sketched. The data revealed distinct isotopic trends with all examples of each component falling within a distinct and limited field.

That such systematic information can be obtained at all emphasizes the importance of taking an inhomogeneous rock apart and analysing the components separately. Failure to do this in the past has often produced fuzzy data with large variations liable to misinterpretation. That such systematic information was actually obtained in this case, however, indicates that no major re-equilibration has occurred since the dolomite was laid down during the Precambrian. Since that time there has been no extensive interaction with meteoric waters, no deep burial, no more than minimal metamorphism and little deformation.

All the indications are, therefore, that the isotopic ratios and trends are original. What's more, those ratios and trends bear a striking similarity to those from primary Phanerozoic limestones. Tucker thus concludes that the Beck Spring Dolomite and, by implication, the many other Precambrian dolomite rocks with comparable properties were precipitated directly as dolomites and thus not generated by the dolomitization of directly precipitated limestones. And as the most important control on carbonates is the isotopic composition of the water from which they are precipitated, the inevitable, or at least the simplest, overall conclusion is that the Precambrian seawater that favoured the production of Ca-Mg carbonates (dolomites) must have been chemically different from the Phanerozoic seawater that gave, and gives, rise to Ca carbonates (limestones).

Unfortunately, Tucker does not elaborate on the difference, except to note the general consensus that the seawater characteristics favouring dolomite precipitation would include a higher than usual Mg/Ca ratio, a higher CO₂ partial pressure, a higher temperature and a lower SO₄²- content. So mysteries remain. Why does dolomite not precipitate from modern seawater if, as Tucker claims, it is favoured thermodynamically? Why experiments to synthesize dolomite under simulated sedimentary conditions merely resulted in an imperfectly ordered, Ca-rich version of dolomite ('proto-dolomite')? Why, if dolomite was the preferred precipitate during the Precambrian, were limestones nevertheless sometimes generated? And when (and why) precisely did the preference change from dolomite to limestone?

What the answers to these questions might say about dolomite is of comparatively minor importance, but what they might say about the evolution of seawater composition could be a rather bigger issue.

Intermediate valence compounds as applicable materials?

from Michael Kelly

UNDER modest pressures, the normally semiconducting samarium sulphide undergoes a first-order phase transition to a metallic state. Thus by rubbing or scribing the surface of this material, an intrinsic metal-semiconductor contact can be generated and can subsequently be removed by temperature excursions of approximately 100°C.

Possible applications of this and other surprising properties of the so-called intermediate valence compounds, especially those involving compounds and alloys of the rare-earth elements, were outlined by P. Wachter (Zurich) in the closing session of a one-day meeting* devoted to the physical properties of the these materials. As the name implies, the ionic constituents of intermediate valence compounds may carry non-integral charges. Briefly, in the solid environment, only a small energy difference may be involved in the transfer of an electron from an incomplete f shell of a rare-earth atom to the available states of the valence band. The result is that there may be dramatic anomalies of physical properties not so far explained by conventional valence band theory.

Wachter opened the meeting with a review of recent work by his team on semiconducting intermediate valence compounds. Because of the weak interactions of electrons in the f shells of adjacent rare-earth atoms, the characteristic energy gaps are of order 10 meV, corresponding to temperatures of order 100K. These are similar to energies associated with magnetic ordering and farinfrared optical absorption, so that small temperature changes can induce substantial changes in many physical properties. The metal-insulator transition under pressure is accompanied by a volume change of order 10 per cent, because of the different size of the rare-earth atom in its different charge states. As an incipient instability, it causes the elastic properties to be anomalous under ambient conditions. Compressibilities are enhanced, some elastic constants are negative and finite wavelength vibrational instabilities are encountered. G. Saunders (University of Bath) reported on these anomalies as the transition is approached. Possible applications as pressure sensors and phonon generators can be envisaged.

The rare-earth metals and their alloys (including those exemplified by Eu Cu₂Si₂) have optical, magnetic and electronic

transport properties that vary as the valence changes (reviewed by D. Wohlleben, University of Koln, and F. de Boer, University of Amsterdam). The valence changes generally take place at low temperatures, so that in ambient conditions most physical properties, though anomalous, are 'quiet'. The metallic alloys are easier to prepare, are simpler to analyse and are proving a fertile testing ground for the current theories of intermediate valence phenomena.

Preparation of pure and stoichiometric sulphides of rare-earth metals is proving difficult (H. Bach, University of Bochum), especially because of the high volatility of sulphur with respect to the rare-earth metals.

The low-temperature electrical conductivity of SmB₆, and its sample dependence in particular, pose unanswered questions that impinge on the transport theories of disordered systems (Sir Nevill Mott, University of Cambridge). The magnitude of the resistivity of TmS and its relative temperature independence below 1K is a further puzzle. Attempts to extract an effective one-electron theory from the general many-electron formulation, in order to account for the anomalies in lowtemperature specific heat and magnetic susceptibility of the metals, were reviewed by D. Newns (Imperial College). Mixed valence materials are those where one species is present in one of two charge states, and they have already found applications, particularly as dyes. P. Day (University of Oxford) cited many other examples, including Fe₃O₄ (magnetite) and LiTi, O₄ (which goes superconducting).

Other points raised in the open-ended discussion included the inability of the compounds to survive more than ten cycles through the pressure-induced phase transition without damage, and the fact that doping (apart from alloying in metals) has not been investigated, as non-stoichiometry is already providing a wealth of phenomena. Catalytic properties have not been examined but were the subject of speculation.

Given our increased understanding of the semiconducting intermediate valence compounds, it remains for further advances in the methods of preparation to be achieved, and a wider characterization undertaken, before they replace existing materials in device applications or forge a new range of devices based on their unique combination of physical properties.

Michael Kelly is at the Hirst Research Centre of the General Electric Company Limited, Wembley, Middlesex HA9 7PP.

^{*}The meeting was held at the Long-Range Research Laboratory at the GEC Hirst Research Centre, East Lane, Wembley, UK, on 15 January 1982

REVIEW ARTICLE

Antibody diversity in lower vertebrates—why is it so restricted?

Louis Du Pasquier

Basel Institute for Immunology, Grenzacherstrasse 487, CH-4005 Basel, Switzerland

Recent studies have revealed that lower vertebrates such as fish, amphibians and reptiles have an antibody repertoire that is much less diverse than that of mammals. It is suggested that the various mechanisms generating antibody diversity are the same in all vertebrates but that non-immunological parameters such as mode of ontogenetic development and cell cycle properties allow fewer somatic events in generating the antibody repertoire of cold-blooded vertebrates.

IMMUNOLOGISTS have always been puzzled by the extent of antibody diversity in mammals, in which the introduction of a single antigenic determinant can stimulate the immune system to produce hundreds of different antibodies. It is difficult to estimate the degree of the huge diversity apparent from these observations: on the one hand counting the genes that encode immunoglobulin gives numbers corresponding roughly to the potential diversity of the system but it is unknown whether these numbers correspond to as many products; on the other hand, by counting products, researchers cannot be sure they are not counting only predominant antibodies, and missing a large number of poorly expressed (therefore undetectable) antibodies. Estimates usually range from 10⁷ to 10⁹ or even more antibodies, speculation in higher vertebrates not being limited by the size of the immune system itself.

We now know that during the ontogenetic development of mouse lymphocytes, various DNA segments assemble and generate a great diversity of genes encoding the variable part of the heavy (H) or light (L) chain of the immunoglobulin molecule. The diversity of the antigen-binding sites resulting from these somatic DNA rearrangements depends on the number of sets and on the number of genes per set. In the most complex case, that of the heavy-chain variable region, the sets V (variable), D (diversity) and J (joining) are assembled to C (the constant-region segment) to form a complete VDJC immunoglobulin heavy-chain gene. There are probably a few hundred V germ-line genes, five J genes and an unknown number of D genes. Since any V gene can assemble apparently with any of the D segments and subsequently to any of the J segments, the diversity generated from this combination is great. It is further amplified by random assembly of the different V heavy chains with light chains to form the complete antigenbinding site. If, in addition, there appear somatic variants due to somatic mutations in the V genes or to joining 'mistakes' during the somatic rearrangement, the potential diversity is further increased (for review see ref. 1). This mechanism, which in mammals uses a large number of inherited germ-line genes and somatic diversification, brings together the once conflicting theories formulated to explain the origin of antibody diversity. However, recent investigations in lower vertebrates indicate that although the antibody repertoire of fish, amphibians, reptiles and perhaps even birds is heterogeneous, it is far less so than in mammals. Two questions immediately arise: (1) does this mean that diversification is achieved by different means in lower vertebrates and in mammals? (2) How can a species survive with such a reduced antibody diversity, or is mammalian diversity necessary? Here I present briefly evidence for reduced heterogeneity of the antibody repertoire in lower species compared with mammals and suggest that the differences are due not only to an evolution of the mechanisms of diversification but also to some non-immunological parameters, such as properties of the cell cycle and the mode of embryonic and larval development.

Low antibody diversity of fishes

Antibody diversity of lower vertebrates has been studied so far by indirect methods based on structural studies, affinity measurements during the immune response, counting isoelectrofocusing (IEF) spectrotypes and by idiotype analysis. No estimate of gene numbers has yet been made in lower vertebrates where immunoglobulin gene analysis is still in its infancy. Some of the methods used are self explanatory: the greater the structural diversity, the number of IEF spectrotypes or the number of idiotypes, the greater the antibody diversity. Affinity measurements have been used to detect an increase in affinity (or maturation of the antibody response). Maturation occurs in mammals and has been interpreted as the consequence of the successive activation of B-cell clones producing different antibodies of increasing affinity. The occurrence of maturation thus implies substantial antibody heterogeneity.

In mammals, a second manifestation of immune response maturation is the successive expression of different isotypes (that is, classes) of immunoglobulin during the immune response. This does not occur in primitive cartilaginous fish, such as the shark Heterodontus francisci, which makes antibodies of the (immunoglobulin M) IgM class only. Both biological and structural data indicate that the repertoire of this species is low. Immunized with 2-furyloxazolone-Brucella, they mount a low-affinity antibody response which varies very little between the different individuals tested and does not increase in affinity after immunization². Although the modified bacteriophage inactivation assay used in these experiments is not ideal for heterogeneity studies because it detects only the predominant antibody in the serum, these results suggest a low antibody heterogeneity both in the species and in individuals; furthermore, the response of this species to a different antigen, pazobenzenearsonate³, has similar characteristics. Limited sequence data on this horned shark immunoglobulin have shown that the variable region appears to be organized in the same way as in higher vertebrates, that is, with a framework and hypervariable regions^{4,5}. The variation between the light chains isolated from different individual animals is, however, very limited, with the major bands having identical isoelectric points. In slight contrast to these results, another species of shark, Ginglymostoma cirratum, immunized with heat-killed pepsinized streptococcal A variant vaccine, produces antibodies that among six outbred individuals have very different light chain gel electrophoresis characteristics⁶. However, as in

0028-0836/82/120311--03\$01 00

Heterodontus, no increase in variation occurs with time after immunization. Interestingly, in Ginglymostoma the heterogeneity of ligand binding involves intramolecular heterogeneity at the conformational level⁷, meaning that a single molecule could have dual specificities.

Although heterogeneous (that is, more than one antibody per antigen), the anti-dinitrophenol (DNP) response of a bony fish, the carp, consists of IgM antibodies that are all distributed between pH 4 and 6.4 on IEF. The number of IEF spectrotypes (1 spectrotype = 1 antigen-binding band) per individual is small (up to 23) and there is little variation from one outbred individual to the other8. There are always several bands observed per antibody type on IEF gels because of deamidation, and in the absence of a reference fish monoclonal immunoglobulin, it is impossible to say how many antibody types the IEF bands correspond to, but certainly fewer than 23. Moreover, some anti-DNP cross-reactive idiotypes are present at a high frequency in an outbred carp population (in all of 11 immunized animals whereas all preimmune sera were negative)9. This does not necessarily mean that the responses of the bony fish lack specificity: their capacity to recognize two Waldenström protein mammalian idiotypes is similar to that of guinea pigs^{10,11}. If mammalian idiotype diversity were equivalent to immunoglobulin diversity, such a result could mean that the fish repertoire is approximately as large as that of the mammal. However, many mammalian immunoglobulins have cross-reactive or even identical idiotypes and differ elsewhere in the molecule, so that idiotype diversity may be much smaller than immunoglobulin diversity. Moreover, it is unknown whether the fish anti-idiotype antibodies are as heterogeneous as those of the guinea pig.

Amphibian immunoglobulin heterogeneity

In amphibians the primitive urodeles express a very restricted repertoire of antibodies, all of the IgM class as in fish¹². They do not respond well to thymus-dependent antigens¹³, which may be due to a lack of T-cell help but could also be due to the limited repertoire. The fact that there are high levels of natural antibodies to several antigens supports the latter hypothesis: if there are few categories of antibodies, all of them are represented at a high concentration in the serum. More data are available for anurans, particularly Rana and Xenopus. Early work 14-17 on tadpoles proved that anuran larvae could respond specifically (with a number of lymphocytes of the order of 106 cells) to many antigens such as bacteriophages, mammalian red cells, protein antigens and hapten-carrier immunogens like DNP and keyhole limpet haemocyanin (KLH); the maturation of the IgM anti-DNP response was also demonstrated in tadpoles and in adults^{18,19}. Larval and adult frogs responded in a heterogeneous manner, as proved by IEF analysis^{15,20,21}. However, the heterogeneity of the response to red cells, DNP or phosphorylcholine is much more restricted than in mammals. The number of IEF spectrotypes per individual varies from 4 (phosphorylcholine) to 20 (anti-DNP) and very probably corresponds to fewer antibody categories. In the species the number of different anti-DNP antibodies may not exceed 40. These numbers are low compared with those recorded in mammals where, for example, anti-DNP spectrotypes can number as many as 500 (refs 22, 23).

In Xenopus, as in the shark, the amino acid sequence indicates low antibody heterogeneity 24,25 : heterogeneous anti-DNP or even non-immune immunoglobulin pools have provided easily interpretable sequences for the first 16 N-terminal residues of both heavy and light chain variable regions. Altogether, the antibody diversity of anuran amphibians has been estimated at $5 \times 10^4 - 5 \times 10^5$ different antibody molecules.

The availability of clones of *Xenopus* has allowed examination of the role of genetically inherited material in the expression of antibody diversity. Isogeneic *Xenopus* produce antibodies to DNP, xenogeneic red cells, or phosphorylcholine whose IEF spectrotypes are identical or very similar between

isogeneic individuals, whereas they may differ among outbred individuals. The idiotypes of the anti-DNP antibodies cross-react to such an extent that they have been considered identical. Both IEF spectrotypes and idiotypes are inheritable through several generations of cloned animals, suggesting that diversity is not only reduced compared with mammals, but is due essentially to the expression of germ-line genes^{21,25}.

Reptiles and birds

Investigation of antibody diversity has been less extensive in . reptiles and birds. In the former, the lack of or difficulty in detecting an increase in affinity suggests low heterogeneity26 Isoelectric focusing data have suggested a low diversity of antibodies against human serum albumin and DNP in chicken²⁷. Sequence data may also be interpreted in support of this as. chicken light chains seem, on two-dimensional gel electrophoresis, to be less heterogeneous than mouse light chains²⁸⁻³⁰. The poor increase in affinity of chicken antibodies to two haptens (DNP and fluorescyl) may again indicate a lower heterogeneity of these antibodies³¹. However, the antibody repertoire of the chicken to streptococcal A vaccine is as large as that of mice³². In summary, it is difficult to compare frog and bird repertoires, because the only antigen for which heterogeneity has been studied in detail in birds and mammals (the streptococcal A vaccine) has not been analysed in frogs. The possibility remains that birds have an antibody diversity lower than that of mammals.

Discussion

To account for what seems a conspicuous difference between mammalian and lower vertebrate antibody repertoire, I shall first consider the known mechanisms for antibody diversification: (1) increase in diversity of a set of germ-line V, D, J genes by accumulation of germ-line mutations during phylogeny; (2) a mechanism of diversification during ontogeny by combining the various V, D and J elements at random; and (3) a mechanism of diversification by somatic mutation, also during ontogeny.

One may first consider the possibility that in lower vertebrates the immunoglobulin genetic system is simpler than in mammals, for example, that the J or D segments are missing or rather that their homologues are not yet independently duplicated but have remained associated with some part of the variable immunoglobulin gene. These animals may also have fewer genes per category, that is, fewer V, J and D segments.

I suggest that the mechanisms of somatic diversification which operate during ontogeny also occur in lower vertebrates, but that they are influenced by elements outside the immune system, such as cell cycle properties and mode of embryonic development, and that these influences may reduce the effect of one or other somatic diversification mechanism, thereby giving the impression that most antibody diversity is of germ-line origin. Given the great homology of structure between primitive fish IgM and mammalian IgM³³ and the homology between the genes for *Xenopus* and mammalian IgM³⁴, it is likely that immunoglobulin genes in lower vertebrates are organized in a way similar to that of mammals, that is, with a rearrangement of gene segments during lymphocyte ontogeny.

The expression of antibody repertoire can then be influenced by the following. (1) How much wastage of lymphocytes is possible in animals in which lymphocytes proliferate quickly, cell numbers are large, and nonsense mutations can occur without jeopardizing survival; then somatic mechanisms for increasing diversity and especially somatic mutation may be not only tolerated but favoured. This is the case in mammals where lymphocytes can be considered 'cheap'. If cells do not proliferate quickly, if the number of lymphocyte generations is small compared with the life of the individual, or if lymphocytes numbers are small, then the somatic events, even if they occur at the same frequency as in mammals, will have a less important

role. The species will then de facto rely more on its set of germ-line genes and any mutants that may occur among them. This situation occurs in cold-blooded vertebrates, where the cell cycle can be prolonged when temperatures are low³⁵, where cells are often big and hence in smaller numbers, and thus where lymphocytes cannot be wasted and can be considered 'expensive'.

(2) In such species there is even more pressure for the quick expression of a repertoire of germ-line genes because development generally occurs outside the mother and remarkably quickly. If an efficient immune system is not developed within a few days after fertilization, the individuals may be easily infected by external pathogens. Then their immune system has no time to select randomly appearing somatic mutants of lymphocyte clones. It seems likely that their protection will be best ensured by the rapid expression of a selected set of germ-line V genes.

Finally, how can lower vertebrates accommodate a lower antibody diversity and is mammalian diversity a necessity? One may consider that the immune system of lower vertebrates has been submitted to less pressure for diversification because of the existence of non-immunological defence mechanisms which they inherited from invertebrates. There exist in

invertebrates^{36,37} and lower vertebrates³⁸ such mechanisms as natural haemolysin and complement-related compounds which can recognize cell surfaces of bacteria or xenogeneic cells, lyse these cells and hence may prevent the immune system of the animals from seeing many antigens, thereby reducing the external pressure for diversification of antibody repertoire.

Although considerably smaller than those of mammals, the antibody repertoires of lower vertebrates can still be considered very efficient as most antigens can be recognized by a lower vertebrate immune system having a repertoire of possibly at most 5×10^5 antibody varieties. This raises the question of the need for the great diversity of mammalian antibodies. It is not proved that all antibody varieties are necessary, some may be unselected products which could be inherent in any system in which there are somatic rearrangements.

It is also possible that evolution of diversification may move back and forth and there is no indication that the state of antibody diversification known in mammals is the best and final form. We may be observing them in a phase of expansion of antibody diversity preceding a phase of contraction.

Evolution of the Iceland hotspot

J-G. Schilling, P. S. Meyer & R. H. Kingsley

Graduate School of Oceanography, University of Rhode Island Kingston, Rhode Island 02881, USA

Mantle geochemical enrichment beneath the Iceland-Faeroes hotspot has been episodic, suggesting that blobs rather than a continuous plume may be rising in the region. Recurring rift propagation southward from central Iceland causing progressive melting of the lower crust followed by the upper mantle, best explains the geochemical variations found along the south-west and south-east neovolcanic zones and their degree of thermal maturity.

ALTHOUGH there is no agreement on a particular model for the origin of Iceland, astride the Mid-Atlantic Ridge, it is generally accepted that Iceland represents an anomalously elevated segment of the Mid-Atlantic Ridge where unusual processes and conditions are superimposed on those associated with simple seafloor spreading.

For example, the Iceland crust is thicker and its structure and composition distinct from that of typical oceanic crust¹⁻⁴. The melting zone beneath iceland seems to extend to greater depth, volcanism is more intense, and its products greatly more

varied than along the submerged part of the Mid-Atlantic Ridge².

The composition of the mantle beneath Iceland is apparently also richer in volatiles and radiogenic isotopes of Sr and Pb than the surrounding depleted asthenosphere (that is, the source of normal mid-ocean ridge basalts)²⁻⁷. Some compositional zoning in the mantle about Iceland may also be present^{2-4,8}.

To complicate matters, geological processes by which Iceland developed do not appear to have been constant in intensity nor necessarily continuous in time. For example, palaeomagneto-

.

stratigraphical studies⁹⁻¹¹ and detailed mapping suggest that the volcanic eruption rate has been variable. In addition, the tectonic evolution of Iceland has been complicated by complex rifting zones jumping occurring intermittently throughout its history, sometimes even producing two parallel rifting zones with activities overlapping in time such as the present south-east and south-west neovolcanic zones (Fig. 1)^{1,12-16}. The presence of the East Greenland-Iceland-Faroes Ridge, however, suggests that such unusual activities have been long-lived, and possibly episodic. O'Nions and Pankhurst¹⁷ have also observed a secular decrease in ⁸⁷Sr/⁸⁶Sr in Iceland rocks or age ranging from 16 Myr BP to the present, suggesting that the source of Iceland volcanic products may have varied with time.

Here we review the geochemical data we have accumulated in the Iceland-Faroes-East Greenland region, emphasizing spatial and temporal rare earth (RE) variations in basalts, as well as comparing known Icelandic rift zones at apparently different thermal and tectonic stages of development. For example, the north-east and south-west zones, which are current landward extensions of the Mid-Atlantic Ridge axis (Fig. 1), are considered to be mature rift zones at a quasi-steady state, exhibiting high heat flow and well-developed extensional tectonics1. On the other hand, the south-east zone, a flank zone parallel to the south-west rift zone, appears to be a younger rifting zone in the process of propagating southward. This rift zone does not exhibit any heat flow anomaly and has only poorly developed extensional features¹. It seems to be at a transient stage of development. In contrast, the Skagi zone appears to be an ephemeral palaeorift which developed ~2.5 Myr BP on the flank of the main rift zone in North Iceland, and subsequently died without reaching maturity^{18,19}. In contrast to the south-east zone, there is no petrological and geochemical evidence suggesting that this ephemeral rift developed by propagation but rather evolved uniformly along its entire length.

We will demonstrate that volcanic products associated with rift zones at such distinct stages of development are also petrologically and geochemically distinct. If this interpretation is correct, we can begin to decipher the thermal and tectonic evolution of Iceland in the more remote past.

Our report is based on rare-earth concentrations (La, Sm and Yb) of 334 basalts broadly distributed throughout Iceland (Fig. 1), and isotopic data published^{3,4,17,20-27}. (La/Sm) and (Yb) indicate chondrite normalized enrichment factors for La/Sm and Yb. A good age control for Pleistocene-Miocene lavas was obtained in eastern Iceland, Vestfirdir, Borgarfjordur and West Iceland by coordinating our sampling with existing age dating and palaeomagnetostratigraphic studies of these regions^{9-11,28-30}. Part of the RE data has been published elsewhere^{2,19}, and the remaining RE analyses can be found in ref. 31.

Temporal variations

Rare-earth patterns of all the Iceland basalts studied are shown in Fig. 2a. There is an important difference in the type and range of pattern for Pleistocene-Miocene (13.5-0.7 Myr) basalts and basalts from the neovolcanic zones (<0.7 Myr). Pleistocene-Miocene lavas are consistently enriched in light-RE, whereas more recent lavas exhibit a wider spread in light-RE from enriched to depleted patterns more like those of normal mid-ocean ridges. The (La/Sm) distribution in Pleistocene-Miocene lavas is normal with a mode around 1.65

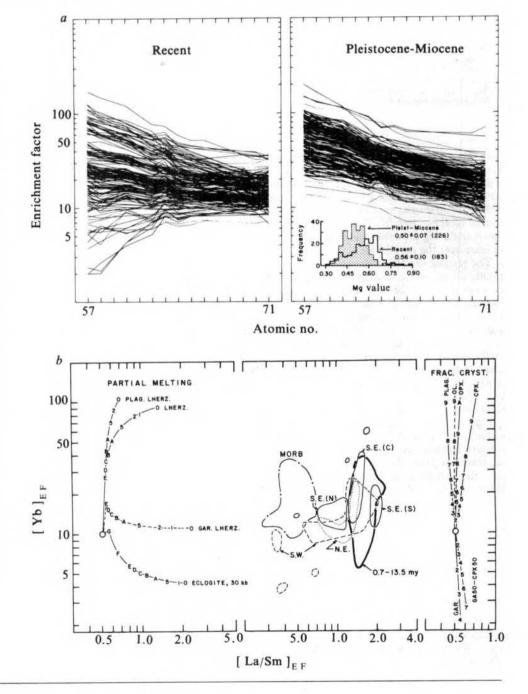

and an average of 1.7 ± 0.27 (1 s.d.), whereas the (La/Sm) distribution in Recent lavas tends to be positively skewed with a mode around 1.35 and an average of 1.34 ± 0.40 . There is also a significant statistical difference at the 99% confidence level in the distribution of Mg-value of Pleistocene–Miocene lavas which is normal with a mode around 0.5, and that of Recent basalts which has a mode around 0.6 and is positively skewed (Fig. 2a). Figure 3 shows that light RE-depleted basalts $\{(\text{La/Sm}) < 1\}$ occurring in Recent time are confined to basalts high in Mg-value (Mg/Mg+Fe²⁺, atomic concentration ratio) representing either olivine tholeiites or picritic basalts as also found by other authors^{18,19,25}. Finally, the new Miocene picritic basalts we have encountered in Vestfirdir are light-RE enriched and not depleted as in Recent time. Thus, light-RE depleted basalts seem to reflect eruption of a basalt type which has clearly developed on Iceland only in Recent time.

The above results suggest a secular decrease in light-RE enrichment from Tertiary to Present which is best illustrated in the Eastern Plateau basalt succession (Fig. 4). A broad regular decrease is readily noted from 13.5 to 2 Myr. Extrapolation of this trend below 2 Myr BP to the zero age intercept coincides

with the mean value found for the north-east neovolcanic zone, which is the locus of the present spreading axis in northern Iceland. The secular variation extends even within the northeast zone where the dormant east fissure swarm is dominated by light-RE enriched basalts, whereas light-RE depleted patterns are more predominant in the now active western fissure swarm mapped by Walker³². Thus this is also apparent in West Iceland between basalts greater and <0.7 Myr BP. The rate of light-RE decrease seems to have increased significantly within the past 0.7 Myr BP.

In addition to the secular decrease in (La/Sm), there is a concomitant secular decrease in ⁸⁷Sr/⁸⁶Sr throughout Iceland suggesting that the mantle source of these basalts beneath Iceland has evolved¹⁷. Such secular geochemical variations are not unique to the past 14 Myr history of the Faeroes-Iceland-Greenland Ridge, but has also been observed during the later period of the Faeroes Island Plateau basalt formation some 55–50 Myr BP, at the onset of continental drift in this region of the North Atlantic^{26,33}. (La/Sm) and ⁸⁷Sr/⁸⁶Sr decrease and ¹⁴³Nd/¹⁴⁴Nd increases as one proceeds from the lower and middle basalt series of the Faeroes^{26,31}. The Plateau basalts

from East Greenland's continental border are similar to the Faeroes upper series, suggesting symmetry about the Mid-Atlantic spreading axis³³. We conclude that the secular (La/Sm) observed both in eastern Iceland, and earlier in the Faeroes, reflect a true secular variation in the composition of the mantle source of these basalts. The enrichments seem to have been episodic during the evolution of the Iceland hotspot evolution at least over the past 60 Myr.

The secular variations shown in eastern Iceland may not be totally devoid of complexity due to spatial variations (Fig. 4). A close look at the broad (La/Sm) secular decrease, may indicate a variation of a shorter wavelength, with a maximum around the 7-8 Myr period. Such a perturbation may be significant as it coincides with a period of high lava extrusion rate^{9,11} and the proposed sudden increase in volcanic activity on the Reykjanes Ridge which apparently initiated the development of time transgressive V-shaped ridges³⁴. However, there is also a 60-km break in the sample profile at this point, and thus the perturbation could also reflect some small but significant spatial variations existing at that time.

Figure 4 further shows that the regular secular trend noted in the Eastern Iceland Plateau is generally not corroborated in western Iceland based on composite basalt profiles from widely separated regions, though basalts from Vestfirdir are statistically indistinguishable from the Eastern Plateau basalts over the same 13.5-9 Myr BP period. This may partly be due to our inadequate sampling which does not permit us to take into consideration possible Tertiary spatial variations along rift strikes, such as those currently found along the neovolcanic zones, and partly due to complications imposed by rift jumping and the probable presence of parallel ephemeral rift zones such as Skagi and possibly Borgarfjordur.

Spatial variations

For practical reasons, our study of spatial variations across Iceland has been limited to known palaeo- or neovolcanic rift zones. We have projected the variation in (La/Sm) and Mg-value within these zones along two major profiles running

essentially parallel across Iceland (Fig. 1): the Eastern and Western Profiles (Fig. 5). Note that all the lavas from the Eastern Profile are essentially contemporaneous, whereas there is an age discontinuity on the Western Profile corresponding to Skagi (0.5-2.5 Myr) and the south-west zone (<0.7 Myr). Clearly there are important RE and Mg-value variations between the neovolcanic zones as well as within them. (La/Sm) and Mg-value respectively decrease and increase northward. along both the south-east and the wouth-west zone, but at a faster rate in the SW zone. On the other hand, 87 Sr/86 Sr appears relatively constant along the entire south-west zone³, but tends to increase southward along the south-east zone^{3,20,21,23,27}. The increase in (La/Sm) along the south-east zone is rather stepwise, and the variation essentially reflects three major petrological zones recognized first by Jakobsson (Fig. 1)^{35,36}. This is not the case along the south-west zone which shows no petrological gradient and is dominated by olivine tholeiites and tholeiites³ In contrast, the (La/Sm) and Mg-value variations in the Skagi palaeorift zone and north-east neovolcanic zone show no well developed spatial trends along strike^{18,19}, although there is a lateral difference in the distribution of RE patterns between the dormant western and the active eastern fissure swarms of the north-east zone32.

Finally, our extensive survey demonstrates that the strongly light-RE depleted picritic basalts previously reported in Central Iceland^{20,23,27} and the Reykjanes Peninsula³⁷ are, in fact, limited to these two regions which have been proposed to be fracture zones^{1,18} (Fig. 5). None were found elsewhere along the neovolcanic zones nor in the Pleistocene-Miocene lavas of Iceland. Only three picritic basalts were observed in our survey of Pleistocene-Miocene lavas, but these have light-RE enriched patterns. The spatial contrast within and between known rift zones of Iceland is further illustrated in (La/Sm) versus Mgvalue plots (Fig. 3). The (La/Sm) appears to be insensitive to

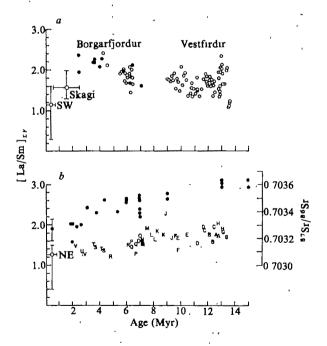

Fig. 4 Secular variation of (La/Sm) through the basalt plateaus in western (a) and eastern (b) Iceland. In a, \bullet , samples dated by the K-Ar method¹⁰; C, samples whose age has been estimated from their stratigraphical height and the assumed linear relationship between stratigraphical height and age from ref. 10 for Borgarfjordur and McDougall and Kristjansson (in preparation) for Vestfirdir. Ages between 13.5 and 10.5 Myr are based on the average K-Ar ages of several profiles while ages between 10.5 and 9.0 Myr are based entirely on field relations relative to older, dated lavas The average (La/Sm) for the south-west (SW), and Skagi zones are shown for comparison, error bars corresponding to the range in age and (La/Sm) observed in each zone In the eastern Iceland series, letters refer to different profiles (see Fig. 1). Ages of samples in this series are based on the palaeomagnetic stratigraphy in ref. 11 The average (La/Sm) in the northeast (NE) zone is also shown. 87 Sr/ 86 Sr data (\bullet) is from ref. 17.

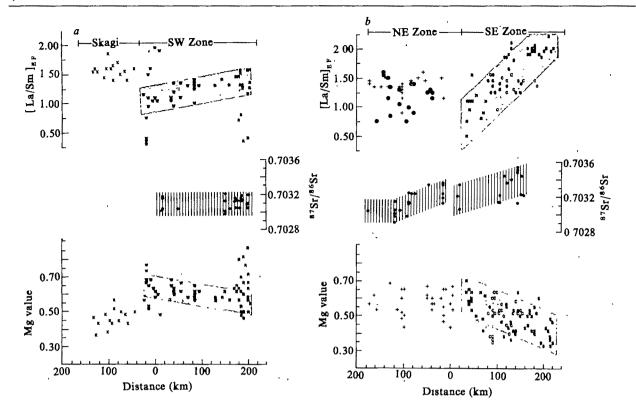

Fig. 5 (La/Sm), Mg-value and ⁸⁷Sr/⁸⁶Sr variations along. a, western (SW and Skagi), b, eastern (SE and NE) volcanic zones. Distance along the abscissa refers to distance away from central Iceland 64.86° N) along the axes of the volcanic zones (see inset Fig. 1). Sample locations have been projected normally to zone axes. Samples from the active western ● and dormant eastern + part of the north-east zone are indicated. Mg-value data for the north-east zone is from ref.

72, whereas the ⁸⁷Sr/⁸⁶Sr variations were constructured from data in refs 3, 4, 17, 20-25 and 27.

Mg-value variation in a particular zone, but the level of (La/Sm) is distinct from one zone to another.

We consider that the distinct (La/Sm) level within each region reflects similar mantle source variations. On the other hand, the different (La/Sm) levels observed within the south-east zone, which also corresponds to three different petrological types^{35,36}, suggest both distinct sources as well as melting conditions.

Model constraints

Although numerous models have been proposed to explain trace element and isotopic variations in isolated regions in Iceland (see refs 22, 23, 25, 38–40), few have been suggested for the entire Iceland plateau and surrounding ridge segments that account for both spatial and temporal variations in a unified way.

In general, processes which have been suggested to affect RE patterns in Iceland basalts range from: (1) fractional crystallization; (2) partial melting conditions in the mantle (such as degrees of melting, mineralogy and dynamics of melt removal); (3) magma-wall rock interaction; (4) zeolitization and spatial variations within eruptive lenses^{41,42}; (5) mixing of different magmas or reservoirs; (6) mantle heterogeneities (of specified or unspecified causes).

Merits of these possibilities are briefly evaluated before we propose our preferred model.

(1) Although it is clear that fractional crystallization took place from the presence of phenocrysts, large (Yb) variation and Mg-value variation within individual zones (Fig. 2b and Fig. 5), such a process cannot account for the (La/Sm) variation observed within a particular region. This is also ruled out in any region where there is a covariation of (La/Sm) and ⁸⁷Sr/⁸⁶Sr, assuming that equilibrium rather than disequilibrium partial melting takes place (Figs 4 and 5).

(2) Variation in degree of batch partial melting is also unlikely to account for the secular variation in RE patterns noted in Figs 2a and 4 as the range of partial melting would be from a few per cent to 100%, and thus is untenable petrologically speaking, considering that the mantle is most probably peridotitic. Of course, some variation in partial melting is likely to take place and is permissible depending on the existing thermal regime, type of lava erupted, and isotopic ratios observed²⁷. The south-west zone is an example where (La/Sm) decreases towards Central Iceland, whereas ⁸⁷Sr/⁸⁶Sr remains essentially constant (Fig. 5), and the south-east zone is an example where ⁸⁷Sr/⁸⁶Sr and (La/Sm) co-vary and the petrological basalt type changes from tholeitic to alkalic (Fig. 5).

Wood's model⁴³ invoking fractional melting is also unlikely to explain the secular variation observed for both the RE and ⁸⁷Sr/⁸⁶Sr (or ¹⁴Nd/¹⁴⁴Nd). It is sufficient to say that the build-up of 87Sr/86Sr with time is irreversible. Once a source region high in 87Sr/86Sr has been established, successive partial melting of such a source region in equilibrium conditions will not decrease this ratio (which has been corrected for any possible isotopic mass fractionation, see ref. 3). It is also improbable that models which consider disequilibrium melting of a veined mantle^{27,44} can explain the observed secular trend over approximately a 10-Myr period of seafloor spreading and the cyclic nature of the Iceland hotspot during the past 60 Myr. This would require a mechanical decoupling of the crust generated by spreading and the mantle source from which melts are derived (that is, decoupling of the crust from the lower part of the lithosphere). This is totally inconsistent with plate tectonic theory, structure of the lithosphere and the distribution of earthquakes. Furthermore, application of the concept of such disequilibrium melting⁴³ for generation of basalts, which seem to have required rather large degrees of melting, does not seem viable on the basis of Hofmann and Hart's⁴⁵ kinetic and scaling analysis.

(3) It is difficult to imagine how magma-wall rock interaction could account for the regular spatial and temporal variation

and cyclic nature of the geochemical variation noted. Indeed, because very *ad hoc* conditions would have to be invoked we reject this possibility.

(4) Wood and co-workers⁴⁰⁻⁴² interpreted the RE variations observed in eastern Iceland in terms of spatial variations within eruptive lenses rather than temporal effects. Wood⁴¹ also suggested that the high (La/Sm) found in the oldest basalts was due to increasing depth or burial and zeolitization of the lava pile. We find Wood's explanations unlikely because: first, basalts of the same age from the Vestfirdir Plateau (9-13.5 Myr), which we have studied because they have not been zeolitized, also have high (La/Sm), indistinguishable from that found in basalts of the same age from eastern Iceland (Fig. 4). Second, Miocene picritic basalts from Vestfirdir are light-RE enriched and not depleted, as Wood suggests for high MgO basalts from shield volcanoes erupted near lens margins, which would have subsequently been eroded⁴². Third, the secular variation shown in Fig. 4 using the new dating scale of Watkins and Walker¹¹ is much smoother than that observed using the scale of Dagley et al.²⁸. This supports our view that the variation is indeed time-related, rather than spatial^{41,42}. Fourth, contrary to Wood's model predicting increasing (La/Sm) with increasing depth of burial and grade of zeolitization; our samples from both the N section within the highest grade laumantite facies and sections J to P in the lower grade mesolite facies fall on the general secular trend shown in Fig. 4, and not above; our basalts from sections A and B which are of similar age and geographical location have similar (La/Sm) despite the fact that section A has undergone a higher degree of metamorphism (mesolite facies) than section B (analcite facies) (Fig. 4); and

this is also the case for sections F and J. Finally, in addition to the secular decrease in (La/Sm), there is a concomitant decrease in ⁸⁷Sr/⁸⁶Sr and an increase in ¹⁴³Nd/¹⁴⁴Nd both on Iceland during (the past 13 Myr (refs 17, 24) and on the Faeroes 60–50 Myr BP (ref. 26). This is too much of a coincidence to be attributed to secondary alteration⁴¹, as for both Iceland and the Faeroes, the (La/Sm) and isotopic trends were established on totally different sample suites. Furthermore, the radiogenic Nd isotopic ratio is unaffected by weathering and mild metamorphism or metasomatism⁴⁶.

(5) Oskarsson et al.⁴⁷ have proposed a petrochemical model for rift zones on Iceland which is consistent with the crustal accretion model of Palmason⁴⁸. Basalt variations are explained by mixing between mantle derived olivine-tholeiites and variable amounts of crustal-derived magmas ranging from silicic to nepheline-normative melts. Flank zone volcanism^{35,36,38} is considered to be dominated by crustal-derived magmas, whereas the main axial rift zones are dominated by mantle-derived olivine-tholeiites (Fig. 1b). A crucial assumption of this model is that the subsiding crust becomes completely hydrated by hydrothermal activity. Studies of DSDP rocks of various ages in the oceans, show that hydration of the oceanic upper crust is very irregular and incomplete, despite the ample abundance of seawater above. It is doubtful that on Iceland where such an abundant source of fluids is absent, complete hydration would in fact take place. Their model also does not consider the temporal, nor spatial, variations found along the main axial zones discussed here. However, magmas of crustal derivation in the southern part of the south-east zone is an attractive

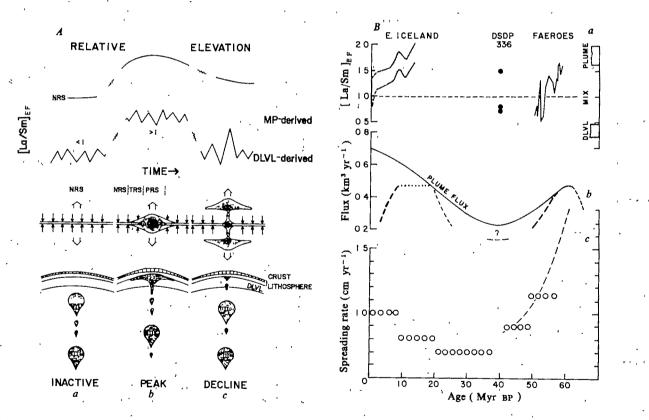

Fig. 6 A, model of a mantle plume (MP) ridge system showing variation in plume flux with time and a cycle in plume (blob) activity that is consistent with geochemical variations observed in erupted basalts. Phases. a, plume is rising beneath an existing spreading ridge (passive spreading); b, plume-flux exceeds the gap created by spreading resulting in blob flattening and spill along spreading directions (active spreading). Plume-derived material dominates the erupted products which accumulate as plateau basalts; c, tailing phase of the blob. Plume flux is insufficient to feed the overlying spreading ridge and material from the depleted low velocity layer (DLVL) compensates Small arrows indicate horizontal component of asthenospheric flow of DLVL material toward the ridge axis. Large arrows indicate spreading directions of the overlying lithospheric plates NRS, TRS and PRS stand for normal, transitional and plume ridge segments B, Reykjanes Ridge spreading rates, Faeroes-Iceland mantle plume flux and (La/Sm) variations with time modified from ref. 33 Curves c are spreading rates by Vogt and Avery. (dotted-dashed curve) and by Herron and Talwani⁵¹ (O). Curve b is the plume flux (solid line) estimated from Vogt and Avery, assuming basalts represent 25% partial melting and, therefore, that basaltic discharge is equal to one-quarter of the total plume flux. The dashed lines indicate our estimate of plume flux for the Iceland-Faeroe plume during the 60-50 (Schilling and Noe-Nygaard 1974) and 13.5-0 Myr periods, based on (La/Sm) as shown in A.

• Data from DSDP site 336 (ref. 51)

hypothesis but the crust need not be hydrated to the extent indicated by these authors.

Preferred model

The binary mixing asthenosphere-plume or blob model proposed earlier (Fig. 6)³³ can readily explain the noted temporal and spatial co-variation of (La/Sm) and ⁸⁷Sr/⁸⁶Sr, but is inadequate when there is a decoupling between these two parameters, such as in the south-west zone (Fig. 5). It also fails to explain readily the southward (La/Sm) and ⁸⁷Sr/⁸⁶Sr decrease along the SE zone since it is of opposite sense to the gradient observed along the Reykjanes Ridge and Peninsula. We propose a composite dynamical model. The blob model explains the secular variation whereas spatial variation such as, for example, along the south-east zone is explained by rift propagation into older crust, resulting in, first, melting of the older large-ion-lithophile-enriched (LILE) lower crust-lithosphere, the enrichment reflecting an earlier stage in blob activity, followed by melting of the upper mantle due to advection.

In the blob model, the RE pattern of a basalt primarily reflects the mixing proportions between a light RE-enriched mantle plume source ({La/Sm}>1(and the asthenosphere which is characteristically depleted in light RE ({La/Sm} \le 0.6) (Fig. 6). The degree of mixing depends on the interplay between the rate of mantle plume upwelling and the rate of lithospheric plate divergence above the upwelling region, both of which are allowed to vary independently through time³³. Figure 6b compares the known temporal variation for the Iceland-Faeroe Ridge with the concurrent variation in spreading rate of the Mid-Atlantic Ridge, and a mantle plume flux, modified from Vogt and Avery's 49 curve for rate of basalt discharge in accordance with our new results. The (La/Sm) decline in the 50-60 Myr period could not be accounted for by a change of spreading rate as spreading would have had to increase rather than decrease³³. Therefore, the (La/Sm) decline must reflect a decrease in plume flux³³. Interpretation of the (La/Sm) secular decline within the past 13 Myr BP in Iceland depends on how reliable the spreading rate estimates are during this period (Fig. 6b)49,50. At face value, the (La/Sm) decrease during the 9-13 Myr period could be accounted for by increasing spreading, but not during the past 9 Myr which again would require a decline in plume flux which would be particularly severe within the past million years. The blob model further suggests that we are witnessing in Iceland the declining phase of mantle blob activity, that is, a rapid change to a more passive mid-ocean ridge type spreading regime. If such a trend is extrapolated into the future, the model predicts either a change from a subaerial to a submarine regime and the possible split of Iceland into two islands located symmetrically about the Mid-Atlantic Ridge, or a new phase of plateau basalt formation, depending on the periodicity and topology of the proposed blobs.

It has been suggested²⁷ that the large (La/Sm) variation observed in successive flows sampled in DSDP Hole 336 on the northern flank of the Faeroes-Iceland Ridge⁵¹, may not support the proposed cycle (Fig. 6). We contend that what happens in the interim period between two blobs depends on the exact topology of the blob tail, that is the nature of schlierens trailing behind the main body of the blob (see ref. 52). Such interim periods may be characterized by inefficient mixing and thus possible alternation of lava with the geochemical signature of one source or the other. Rapid fluctuation between light-RE enriched, and depleted patterns is also observed on the Reykjanes Peninsula^{25,37} as well as in the later phase of volcanism on the Faeroes just before the spreading began.

The blob-asthenosphere mixing model is supported by the detailed nature of the RE patterns shown in Fig. 2b. There is a (La/Sm) gap between <0.3 and 0.4 which corresponds to the field occupied by normal ridge segments adjacent to Iceland⁸. (La/Sm) variations on the right of this gap are explained by mixing the blob and depleted asthenospheric material whereas

to the left fractional melting is probably the cause of such unusually light-RE depleted picritic basalts which seem to occur only in Recent time, as previously suggested 19,43,44.

We further propose that the spatial variation in RE patterns and petrological basalt types found along the recognized neovolcanic and palaeorift zones of Iceland seems to depend on the degree of thermal and tensional tectonic maturity of the zones and existing mantle source heterogeneities beneath them. The northward progressive decrease in (La/Sm) and the increase in Mg-value observed along both the south-west and south-east zones, but at a faster rate in the south-east zone (Fig. 5), are best explained by a temporal change in intensity and conditions of melting resulting from rift propagation. For example, the south-west zone, a direct extension of the Mid-Atlantic Ridge exhibits high heat flow and well developed extensional tectonics¹ which we interpret as reflecting maturity¹9, whereas such features are lacking in the south-east¹, thus suggesting youth.

The thermal process resulting from such rift propagation is best described in two stages, though in reality it probably evolves more continuously. We assume first that crustal tension released at the tip of the rift propagator evolving along the south-east zone is sufficient to bring the older and colder late Miocene lower crust (~8 Myr old) into the partial melting stability field, resulting in magmas of crustal origin (and perhaps old lithosphere as well) with Sr and Nd isotopic signatures of late Miocene lavas exposed elsewhere on Iceland 17,20,24. RE patterns will also be light-RE enriched, but detailed modelling is required to take into account the possible mineralogical composition of the lower crust (and old lithosphere), degree of melting and type of lavas generated31. As spreading develops and the rift matures, there is a progressive change from primarily crustal-derived products to basaltic melts derived from mantle advection. We have seen earlier that the mantle source on Iceland in Recent time, particularly within the past 700,000 yr has become significantly diluted with light-RE depleted asthenospheric material. Thus, basalt erupted in a later stage, far beyond the tip of the rift propagator, will also be lower in ⁸⁷Sr/⁸⁶Sr, higher in ¹⁴³Nd/¹⁴⁴Nd (ref. 24), and less light-RE enriched. In other words, in this model the present spatial variation observed along the south-east zone is, in fact, the result of a temporal evolution in melting intensity and conditions, due to rift propagation. Melts erupting near the tip of the propagator are primarily derived from the older late Miocene lower crust-lithosphere, whereas in the northern part, as rifting and melting increase, basalts are derived from a mantle plume-asthenospheric mix, now dominated by the latter type of material. Increasing melting towards the centre of the plume (central Iceland) is supported by a concomitant increase in ²³⁰Th /²³²Th /²³²Th /²³⁴ 523 Th Th/232Th (ref. 53) and an increase in volcanic delivery rate which is manifested by a widening of the rift zones and a greater abundance of central volcanoes 13,35,36. The tip of the present rift propagator along the south-east zone probably lies just south of Surtesy Island, which emerged in 1963. Whether such a propagating rift is of the membrane type⁵⁴ as suggested for the Vestmannaeyjar-Surtsey Zone and the Settla Peninsula55, or of Hey's type⁵⁶ is uncertain.

We also suggest that the south-west zone may also have developed by rift propagation, but earlier relative to the south-east zone, that is some 6 Myr BP (ref. 57). This is indicated by: (1) the similarity but different intensity of the gradient in (La/Sm) and Mg-value between the two zones (Fig. 5); (2) the presence of a well developed heat flow pattern and extensional tectonics in the mature south-west zone and their absence in the south-east zone¹; and (3) the presence of a ⁸⁷Sr/⁸⁶Sr gradient along the south-east zone but its absence in the more mature south-west zone (Fig. 5). Recent basalts erupted along the more mature south-west zone are all derived from the upper mantle composed of a blend of LILE-enriched blob and LILE-depleted asthenospheric material, with the degree of melting increasing slightly towards the centre of the plume (central Iceland) to account for the small northward decrease in (La/Sm) (Fig. 5)¹⁹.

If our assumptions concerning petrological and geochemical types and degrees of maturity of neovolcanic rift zones are correct and applicable to the more remote past, the following suggestion can be made on the nature of rifting throughout Iceland's history. Generation of the Eastern Plateau and the north-east zone lavas during the past 13 Myr seems to have been associated with continuous spreading and decreasing blob flux into the source region, and has been accompanied by flank rifting activity at least once in the past along the Skagi zone some 2.5-0.7 Myr BP. However, the petrological and geochemical uniformity of basalt erupted along the Skagi zone 18,19 precludes that it developed by rift propagation. Thus, so far there is no evidence for rift propagation in northern Iceland. In contrast, the tectonic evolution of southern Iceland has been complicated by recurring southward propagation of rifts of ephemeral duration and simultaneous flank zone volcanism, as evident in the Borgarfjordur region (7-2 Myr), the south-east zone and the Setberg volcanic region on the Snaefellsnes Peninsula⁵⁸. This evolution is generally consistent with the tectonic evolution models proposed for Iceland 12,14,57. However, there are many uncertainties and several discrepancies which cannot be discussed further without more extensive field work in coordination with additional rock dating and geochemical and petrological studies.

Problems

Although our new data on Iceland support the blob model for the evolution of the Iceland-Faeroes hotspot, the genesis of such enriched blobs remains uncertain. The fact that such mantle material is enriched in the radioactive heat-producing elements (U, Th and K) could suggest a model by which internal heating of a deeper mantle layer rich in these elements would cause the layer to become gravitationally unstable and to rise in the form of blobs^{3,52}. Another possibility is the recent model involving lithosphere recycling⁵⁹. However, this is not supported by the high ³He/⁴He ratio of lavas near and on Iceland^{60,61}. The fact that such anomalous mantle regions are also richer in volatiles^{5,7,62} has also led to the suggestion that metasomatism of the upper mantle^{25,41,62,63}, perhaps resulting from fluids released from deeper mantle convection⁶², has produced the observed enrichments. In the latter case, interstitial fluids rising through the mantle and sweeping out large incompatible ele-

ments, accumulate in the upper mantle below the lithosphere. Such volatile enrichment would also enhance melting by lowering the melting point of the upper mantle and account for the greater volcanic flux in such regions. Application of this model to the Iceland-Faeroe Mid-Atlantic Ridge System would require that such a metasomatic front be geographically localized, spatially zoned, and episodic.

The above possible plume models are not necessarily exclusive. In fact, there is growing evidence that different plumes have different chemical and isotopic signatures and possibly different origins^{8,64}. Some may be related to lithosphere or crustal recycling; others may have a more primary origin^{60,61}.

Another point, inherent of the method of using lavas to constrain possible mantle flow geometries, is whether the gradients found along the Reykjanes Ridge²⁻⁴ reflect a similar zoning of the underlying mantle, or if they reflect a dynamical mixing condition of plume with depleted asthenospheric derived material during generation of new lithosphere². Distinction between these two possibilities would facilitate the choice between the plume or blob model and the metasomatic model. The difficulty lies in the fact that we do not know from what volume and geometry (topology) of the mantle a lava flow erupted on the Earth surface is derived from, has equilibrated with and thus is compositionally representative of. As an example of two possible extreme cases, we ask, is magma along the ridge axis derived primarily from a vertically deep and narrow column of mantle, or alternatively, laterally from a relatively thin mantle layer? Large lateral movement of magmas^{2,65,66} along strike during dyke propagation is also likely to add further interpretative complications.

Until these two major problems are resolved little advance can be made in choosing between the blob and metasomoatic models, or other models including the veined mantle, or vertically zoned mantles of one type or another (see refs 67-69).

A more detailed discussion of the data can be found elsewhere^{31,70}.

This work was partly supported by NSF grants DES75-03997 and EAR77-23736 to J.-G.S. and H. Sigurdsson. Field work and petrological studies were carried out in collaboration with H. Sigurdsson. We thank Rannsoknarad Rikisins for permission to collect samples in Iceland, also Frank DiMeglio, Mike Doyle and staff of the Rhode Island Nuclear Center for their assistance in neutron activation analyses, and Gloria Nappi for assistance.

Processed genes: a dispersed human immunoglobulin gene bearing evidence of RNA-type processing

Gregory F. Hollis*, Philip A. Hieter*, O. Wesley McBride*, David Swan* & Philip Leder*§

* Laboratory of Molecular Genetics, National Institute of Child Health and Human Development; † Laboratory of Biology, National Cancer Institute; ‡ Laboratory of Cellular and Molecular Biology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA § Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA

A dispersed immunoglobulin pseudogene carries two hallmarks of RNA processing—spliced J and C regions and a poly (A)-rich tail. Its discovery strengthens the notion that processed genes are a significant feature of the mammalian genome and that genetic information can return to the genome via an RNA intermediate.

ONE of the α -like globin genes of the mouse has undergone two curious rearrangements; it has cleanly lost both its intervening sequences^{1,2} and it has moved from the active α -globin locus to another chromosome^{3,4}. This association of gene movement and precise splicing suggests that an RNA intermediate might have been involved in the formation of this novel gene1 as well as in its conveyance to a new location3.5. The additional finding of multiple, distantly related members of the globin gene family3 further suggests that this gene is not an isolated example, but rather that dispersed and possibly spliced genesor 'processed genes' as we shall refer to them-represent a significant class of genetic element and are the result of a major mechanism of genomic evolution. (By processed genes we refer to gene-like sequences that, as opposed to their normal counterparts, bear some evidence of RNA-type processing; for example, coincident homology to the site of transcriptional initiation, clean loss of intervening sequences or coincident homology to the site of poly(A) addition, possibly including elements of a poly(A) tail.)

Here we describe a human gene sequence that fulfills these expectations in a particularly interesting way. The gene is a pseudogene corresponding to the human immunoglobulin λ chain, the major locus of which is on human chromosome 22 (refs 6, 7) wherein the normal gene is represented in at least six non-allelic copies⁸. This pseudogene, $\lambda \psi 1$, is no longer at this locus, but has been conveyed to another chromosome. Here it is no longer represented as discontinuous J- and C-region segments, but rather the J and C regions are cleanly joined, again in accordance with the rules of RNA splicing. The gene bears an additional hallmark of RNA processing; its homology to the normal immunoglobulin gene ends abruptly in a long sequence of adenylic acid residues that resembles a poly(A) tail. These facts, in addition to the curious state of the 5' ends of this and the α -globin pseudogene, lead to a minimal—though entirely speculative-model that invokes an RNA intermediate in their formation and conveyance.

Identification and cloning of the λ -like genes

Our previous studies of the immunoglobulin λ light-chain genes of man had shown them to be arranged within a complex locus consisting of six constant region (and presumably at least an equal number of J region) genes, arrayed along a \sim 45-kilobase (kb) stretch of DNA on human chromosome 22 (ref. 8). When cleaved with the restriction endonuclease EcoRI, these genes fall into three fragments, usually 16, 14 and 8 kb long. The smallest (8-kb) fragment occasionally exists in one of several polymorphic forms, the most prevalent one in populations we have analysed being 18 kb. Several other more faintly

hybridizing fragments can also be identified by high-resolution gel electrophoretic analysis or by direct gene cloning. These include a large (>20 kb) fragment, an 18-kb fragment that underlies the strongly hybridizing 18-kb polymorphic fragment, a 16-kb fragment and a small 5-kb fragment that is evident in all human samples analysed. We have also cloned an additional, strongly hybridizing 14-kb fragment that has not yet been linked to the major locus.

The complexity of the human λ locus and its accompanying array of faintly cross-hybridizing gene fragments is reminiscent of the situation encountered among the mouse globin genes^{1-4,9-11}. The more distant relationship between the active λ genes and their structural relatives encoded on the >20- and 5-kb fragments is shown by high and low stringency in in situ hybridization experiments in which cloned active λ constantregion genes and a faintly hybridizing clone, $\lambda \psi 1$, are hybridized to total human genomic DNA (Fig. 1). When active gene sequences (genes 1 and 2 in Fig. 1, corresponding to the Mcg and Kern Oz genes) were used as probes, four strongly hybridizing bands were seen. Each corresponds to the four fragments that can be derived from the active locus of an individual polymorphic for both the 8- and 18-kb active fragments. In addition, faintly hybridizing >20- and 5-kb bands can be visualized in these high stringency conditions, and appear as more intensely hybridizing bands when the stringency of the washing conditions is reduced from 52 to 45 °C. The relative intensities of the >20- and 5-kb bands further suggest that the latter band is more closely related in sequence to the active genes than is the sequence encoded on the larger band (although it is also possible that the larger band is transferred less efficiently to the blotting paper or has a smaller segment of homology).

In any case, these blotting and cloning experiments, coupled with our inability to link the cross-hybridizing >20-, 18-, 16-, 14- and 5-kb fragments to the active locus through map extension strategies using cloned gene libraries (ref. 8 and P.H., G.H. and P.L., unpublished observations) raised the possibility that these fragments also encoded dispersed gene sequences. Therefore, we performed structural and gene mapping experiments on one of the most closely related of these, the 5-kb fragment referred to as $\psi 1$. It was cloned from purified genomic fragments of human lymphocyte DNA using the human λ constant-region probe in conditions of relaxed hybridization stringency (Fig. 1). Hybridization of the cloned, distantly related $\lambda \psi 1$ subfragment back to the genomic DNA exhibits the reciprocal pattern of fragments identified by the active λ gene probe (Fig. 1, lane d); that is, strong hybridization to the 5-kb fragment (itself) and weak hybridization to the active λ genecontaining fragments.

© 1982 Macmillan Journals Ltd

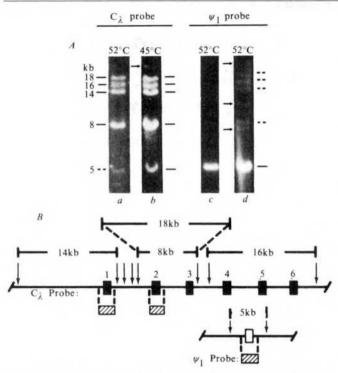

Fig. 1 Identification of cross-hybridizing DNA fragments related to human immunoglobulin A genes. Genomic DNA was extracted from human spleen cells32, digested with EcoRI restriction endonuclease, size-fractionated by agarose gel electrophoresis (10 μ g per lane), transferred to nitrocellu-lose³³, hybridized with ³²P-labelled C λ (a,b) or ψ 1 (d)³⁴, washed in 0.1× SSC, 0.1% SDS at 52 °C (a, d) or 45 °C (b), and visualized by autoradiography. A control lane containing the cloned 5-kb EcoRI fragment is included (c). DNA fragments showing strong hybridization at 52 °C to the $C\lambda$ probe (a) are the 8-, 14-, 16- and 18-kb $C\lambda$ gene-bearing EcoRI fragments. In addition, a 5-kb EcoRI fragment hybridized weakly at 52 °C. When the stringency of the wash conditions was lowered to 45 °C (b), the 5-kb EcoRI fragment hybridization increased. This fragment was cloned and a 750-bp PstI fragment was shown to contain homology to CA. When this 750-bp fragment (see $\psi 1$ probe (B)) was hybridized to the cloned 5-kb EcoRI fragment (c) or human spleen DNA (d), a 5-kb EcoRI fragment hybridized strongly. The 8-, 14-, 16- and 18-kb CA gene-bearing fragments hybridized weakly (d) in these conditions. Four additional bands can be seen hybridizing very weakly and are indicated by arrows (see b and d). The Cλ probe (0.7-kb EcoRI fragment containing coding and flanking sequences of the human A Mcg gene and a 3.4-kb EcoRI-HindIII fragment containing coding and flanking sequences of the \(\lambda \) Kern \(\Oz^+ \) gene) and the \$\psi 1\$ probe (0.75-kb PstI fragment containing \$\psi 1\$ J-C processed gene) are shown in B.

Comparison of the active and pseudogene sequences

The region containing the λ -like sequence was subcloned from the $\lambda \psi 1$ hybrid phage and its nucleotide sequence determined according to the strategy shown in Fig. 2B. Similarly, the sequence of an active λ gene (gene 1, Fig. 1, $Kern^-Oz^+$) was determined for comparison. The two sequences (Fig. 2A) are extensively homologous over the region that corresponds to λ constant region (positions 108–540). Nevertheless, several insertions and deletions alter the $\lambda \psi 1$ sequence so as to create missense runs and termination codons, rendering it a pseudogene.

The points of divergence between the two genes are highly significant. On the 5' side of the sequence, homology ends at the border of the intervening sequence that would have been expected to separate C and J regions in a normal λ gene. A consensus RNA splice site, CCGCAG (PyPyNPyAG), present in the normal gene, is absent from the pseudogene. At the 3' side, homology ends abruptly 26 nucleotides to the 3' side of the putative poly(A) addition signal (AATAAA) that is conserved in both genes. In the pseudogene, the sequence has been replaced at each of these points of divergence by what seems to be evidence of RNA-type processing. The sequence on the 5' side closely resembles a J region complete with reasonable

5' V-J recombination signals spaced the required 12 bases apart 12,13. This homology to an authentic J region can be shown by comparing its nucleotide sequence with that of a known mouse J region (59% homology) and by comparing its translated amino acid sequence with that of a known human λ chain (Fig. 3). The sequence on the 3' side is replaced by a 33-base long poly(A) sequence interspersed with four C and two G residues. The comparable sequence in the active gene is T-rich. Also, a 9-base sequence occurs precisely at the termination of the poly(A) sequence (positions 673-681; Fig. 2A) that is repeated in the 5' portion of the processed gene (positions 15-23; Fig. 2A). This 9-base direct repeat may be the result of an insertion site duplication. In sum, the two sequences diverge from one another at sequences in the pseudogene that resemble those set in place by the two hallmark reactions of RNA processing, the splicing of coding sequences and the addition of poly(A)

Although the pseudogene closely resembles a processed mRNA rather than an intact gene in these important respects, it differs from a normal mRNA sequence in one important way. An active immunoglobulin gene is formed by the joining of a germ-line V region to a germ-line J sequence 12-14. In a few examples thus far studied, the site of transcriptional initiation of these active genes is provided by the incoming V region. Thus, the normal transcriptional initiation site is ~30 nucleotides 5′ from the beginning of the V-region coding sequence 15. The pseudogene sequence noted above completely lacks a joined V-region sequence and indeed retains a reasonable copy of a V-J (DNA) joining signal. Therefore, its similarity to a normal mRNA breaks down in that it lacks the 5′ portion of a normal λ mRNA, the V region, and hence lacks homology to a normal immunoglobulin promoter. We shall return to this problem below.

The processed pseudogene is also dispersed

The initial example of what we refer to as a processed gene, the mouse $\alpha\psi 1$ sequence, resides on mouse chromosome 15, whereas the active mouse α -globin locus is on chromosome 11 (refs 3, 4). Evidently, this processed gene must have been conveyed by some transpositional mechanism from the major globin locus. As gene movement might have a significant role in the formation of processed genes, it was obviously of great importance to determine whether or not the processed λ sequence could be linked to the main λ locus on chromosome 22 (ref. 6). The relationship of these genes was determined in mouse \times human hybrid cell lines that retain different human chromosomes by detecting characteristic restriction endonuclease fragments corresponding to each gene in the various hybrid cell lines 16.

Figure 4 gives an example of such an analysis. Cell line 2 retains the active genes as well as the processed gene, while cell line 1 retains only the active genes. In contrast, cell line 8 retains the pseudogene, but lacks the active genes. As cell lines 1 and 2 retain chromosomes 22 and the cell line 8 does not, these results are consistent with the absence of the processed gene from the normal λ locus on chromosome 22. Similar studies on 24 hybrid cell lines are consistent with this conclusion $(\lambda^+, \psi \lambda^+, \text{ three cell lines}; \lambda^-, \psi \lambda^+, \text{ six cell lines}; \lambda^+, \psi \lambda^-, \text{ three cell lines}; \lambda^-, \psi \lambda^-, 12 cell lines; data not shown), but they do not yet allow us to specify unambiguously the chromosomal location of the processed gene.$

Evidence of RNA-type processing

The spliceless α -globin pseudogene initially suggests that its formation might have been mediated by its processed RNA transcript^{1,2}, and this is supported in several important respects by the discovery of the immunoglobulin processed gene described here. First, the λ -processed gene also bears evidence of two RNA processing events; it has lost its intervening sequences in accordance with the rule of RNA splicing and, like the globin processed gene, its homology with its normal counterpart ends abruptly at a poly(A) addition site. However, unlike the

globin processed gene, its sequence at this point is joined to an extensive poly(A) region (Fig. 2). These features support the notion that processed RNA transcripts were involved in the formation of both genes.

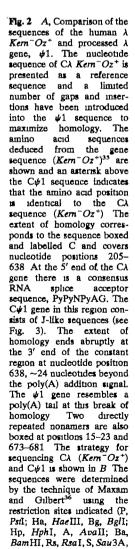

But what of the 5' ends of the two processed genes? Neither of these resembles that of its normal mRNA analogue. The globin sequence homology extends beyond the site of normal transcription initiation and the immunoglobulin sequence clearly has no normal counterpart to the 5' portion of an active λ mRNA. It is therefore clear—if these processed genes were formed from RNA transcripts—that they were aberrantly initiated. (There is some evidence for the formation of such aberrant transcripts in globin and immunoglobulin-producing cells¹⁷⁻¹⁹.) If this is indeed the case, it follows that this 'aberrant' transcript contains genetic information normally excluded from mature mRNAs.

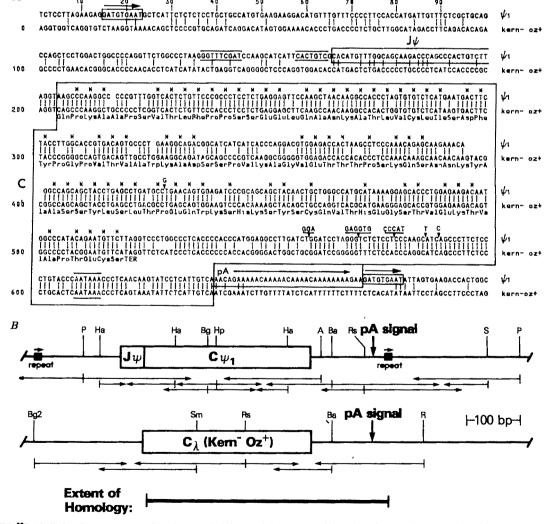

Potential mechanisms for processed gene formation and conveyance

Goff et al.⁵ have noted several useful features of the retroviruses that might account for the conveyance and structure of processed genes. A genomic fragment of DNA, once incorporated into a retrovirus sequence, could be processed so as to lose its intervening sequences during the RNA phase of the viral life cycle. Indeed, there are several examples of incorporate host genes that are represented in spliced form in the retrovirus^{5,20}. However, for such a vector to have incorporated one

of the processed globin or immunoglobulin genes, we would have to postulate a special mechanism to explain how the sequence homology of the processed genes ends at the poly(A) addition site. This feature suggests that the sequence would have to have been taken up as a processed RNA rather than first incorporated, unprocessed, into the retroviral sequence. While this does present a difficulty, gene mapping studies indicate that two retrovirus-like sequences flank the processed α -globin gene, although their configuration does not accommodate a simple model for the role, if any, a retrovirus may have had in their formation²¹.

Two other classes of genomic sequence have also recently been implicated in the formation of processed genes. These are multi-gene families that correspond to the middle repetitive Alu genes²² and the multiple snRNA genes that encode the ubiquitous small nuclear RNAs prevalent in human (and other) . Members of both gene families are transcribed into small RNAs of unknown function²⁴⁻²⁷, the Alu sequence apparently in response to RNA polymerase III²⁸, the snRNA sequence in response to RNA polymerase II²⁹. Although there are multiple active copies of both gene sequences, recent structural studies suggest that many members of these repeated families are pseudogenes, that is, genes that differ from the major expressed version of the sequence^{23,24}. In addition, several features of these genes are similar to integrated transposons: they are flanked by short direct repeat sequences reminiscent of target site duplications, and they are dispersed in the sense that they do not occur in large tandem arrays. (A curious 3.6-kb insertion

Bg2, $Bg\Pi$; Sm, SmaI; R, EcoRI. ¹²P-labelled ends are represented by short vertical lines and the extent and direction of sequencing are indicated by arrows. The boxed area of $C\lambda$ (Kem^-Oz^+) indicates the coding region (amino acids 108-215 of λ polypeptide) and 3'-untranslated region of the mRNA. The boxed area of ψ 1 indicates the sequence that corresponds to J- and C-type sequences. Extent of homology between these genes is shown by a bold black line.

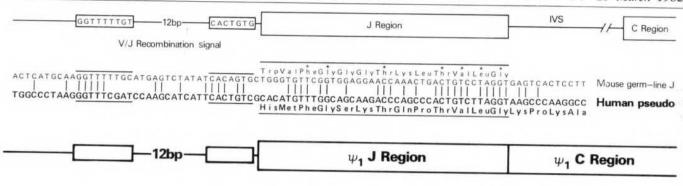

Fig. 3 Comparison of the J-like region of the processed λ gene, $\psi 1$, to a germ-line mouse λ J-region sequence and a typical human J-region amino acid sequence. The nucleotide sequence of $\psi 1$ J region is compared with the nucleotide sequence of a mouse germ-line J region³⁷. The amino acid sequences deduced are shown above and below the nucleotide sequences and an asterisk above the mouse germ-line J amino acid indicates that the amino acid position is identical to the human $\psi 1$. A typical human V-J-C sequence determined at the protein level³⁸ is also shown and an asterisk above the human protein sequence indicates that the amino acid position is identical to the human $\lambda 1$. In addition to the homology seen in the J coding region, the human $\psi 1$ contains remnants of the V-J recombination signal seen in the germ-line sequence of the mouse (indicated by horizontal lines above and below the nucleotide sequence). The homology between the mouse germ-line J and human $\psi 1$ breaks down 3' to the J region, an area where the mouse sequence corresponds to intervening sequence, while the human $\psi 1$ is homologous to CA sequence.

GlySerAspAsnPheValPheGlyThrGlyThrLysValThrValLeuGlyGlnProLysAla Typical human V/J/C

has been found in a *Drosophila* ribosomal gene that is bracketed by 13-base pair (bp) direct repeats³⁰. Careful review of this sequence shows it to end in an A-rich sequence near a poly(A) addition signal.) An additional feature of the two former classes of pseudogene is that their 5' ends, unlike the processed genes we have described, coincide with the normal transcription initiation sites of their RNAs. This fact, and the fact that some, but not all, of these pseudogenes terminate in a poly(A) sequence, have led two groups^{23,24} to propose that they represent a class of transposable element that passes through an RNA intermediate.

Keeping these more detailed proposals in mind, we will consider a minimalist model for the formation of the globin and immunoglobulin processed genes (Fig. 5). First imagine that these processed genes arise from aberrant transcripts that begin at some distance 5' to the genes' normal initiation sites. These transcripts are processed, coding sequences are spliced and poly(A) added. The RNA is converted to DNA and then re-integrated into chromosomal DNA. It is also conceivable that a special sequence has been incorporated into the processed transcript that is necessary for its integration, for example, a retrovirus sequence as suggested by Goff et al.⁵, or an Alu or snRNA element as suggested by Van Arsdell et al.²³ and

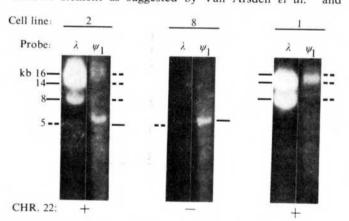

Fig. 4 Discordance of normal and processed λ genes in mouse × human cell hybrids. DNA isolated from somatic hybrid cell lines was digested with EcoRI, fractionated by agarose gel electrophoresis (30 μ g per lane), transferred to nitrocellulose³³, hybridized with a human $C\lambda$ probe or $\psi 1$ probe (see Fig. 1)³⁴ and visualized by autoradiography. Human chromosome 22 carries the active human λ gene locus and is present in cell lines 2 and 1 (ref. 6). The 5-kb EcoRI fragment containing $\psi 1$ gene segregates discordantly with chromosome 22 because it appears in cell line 8 (a cell line that does not contain chromosome 22) and does not appear in cell line 1 (a cell line that does contain chromosome 22).

Jagadeeswaran²², or some other, undiscovered, sequence that shares the mobility properties tentatively ascribed to these elements. Such mobility elements would not normally be transcribed into mRNAs because they lie beyond the usual transcription boundaries of an active gene. Remember that these hypothetical events must have occurred in a germ cell where transcription boundaries and gene activities may differ dramatically from those found in terminally differentiated cells.

If integration of a processed gene does not require a specific integration element and is a fundamental property of any RNA or its cDNA cognate, processed genes might arise from any transcribed sequence. If so, we would expect eventually to find a processed gene that corresponds precisely at both 5' and 3' ends to a normal mRNA. On the other hand, if a mobility element is required, we might expect to find copies of the mobility element still encoded near the parental locus and homologous to a sequence that has been transposed with the processed gene. We might also expect this element to be present near other processed genes. Finally, since we might expect that such sequences would remain a source of these processed genes for a long period of evolutionary time, we might expect to find further examples of processed genes that originate from the

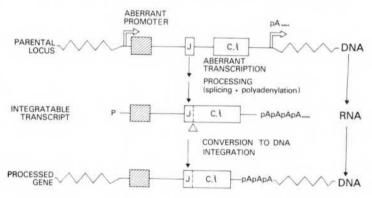

Fig. 5 A minimal model for the formation of the processed Cλ gene. The top line represents the germ-line configuration of the putative ancestral Cλ gene, showing (in boxes) the J and C coding regions as well as the site of a proposed aberrant promoter (arrow) and of poly(A) addition (arrow). The hatched box represents a hypothetical sequence that might render a transcript of this region integratable, a detail that is not required if we assume that any RNA sequence (or its cDNA cognate) can ultimately be integrated into chromosome DNA. The proposed scheme simply calls for an aberrant transcript of this sequence to arise in a germ cell, be processed as an RNA (spliced and polyadenylated), then be converted into DNA for subsequent (or simultaneous) incorporation into a new chromosomal location. Note that information flows from DNA to RNA back to DNA.

affected member of the active gene family. We already know that there are additional, unlinked copies of both genes that are processed gene candidates. It is therefore possible that processed genes represent a major class of genomic element and, while several mechanisms are available for their conveyance, their structures strongly support the notion that RNA transcripts have been involved in their formation. Consistent with this notion, N. Cowan and colleagues (personal communication) have discovered an interesting human α -tubulin-like

pseudogene that has lost its intervening sequences and ends in a poly(A) tail. We expect many such processed genes will be discovered as other multi-gene families are examined in greater detail. Thus, the notion that information can flow from DNA to RNA back to DNA, long established in the case of the retroviruses³¹, seems to involve non-viral genes as well.

Immunoglobulin heavy-chain expression and class switching in a murine leukaemia cell line

Frederick W. Alt*, Naomi Rosenberg †, Rose J. Casanova†, Elise Thomas & David Baltimore

Center for Cancer Research, Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA † Cancer Research Center, Tufts University School of Medicine, Boston, Massachusetts 02111, USA

A cell line that switches from μ to $\gamma 2b$ synthesis during growth in culture uses the same V_H region for both heavy chains but retains two copies of the C_{μ} gene. This suggests that the μ to $\gamma 2b$ class switch can occur, at least in part, by an RNA processing mechanism. Regulatory variants of this cell line lose constitutive μ -chain synthesis but simultaneously acquire lipopolysaccharide(LPS)-inducible synthesis of that chain. This co-variation is allele-specific and is correlated to a large deletion of DNA in the J_H - C_μ intron.

INFECTION of murine bone marrow or fetal liver cells with Abelson murine leukaemia virus (A-MuLV) transforms a small fraction of the cells into clonal, continuous cell lines¹. Various properties of these lines indicate that they are generated from immature cells of the B-lymphoid (immunoglobulin-producing) cell lineage, the majority being related to the most immature cell known to occur in this pathway, the 'pre-B' cell²⁻⁴. Surveys of the structure and expression of immunoglobulin genes in large numbers of such lines have proved extremely useful for defining the pre-B stage of differentiation at a molecular level. In addition, these studies have defined specific subclasses of A-MuLV transformants which exhibit individual aspects of the immunodifferentiation programme. One such cell line is 18-8, and its clonal derivative 18-81, which usually produces μ chains in the absence of detectable light chains² but from which certain clonal isolates also produce κ chains after stimulation with bacterial lipopolysaccharide (LPS). The latter phenomenon is probably due to productive κ -gene rearrangement during growth of the 18-8 line in culture^{5,6}. Synthesis of γ -related

chains has also been detected in populations of these cells² and in subclones of these lines. The work of Burrows et al. 7. together with our preliminary studies⁵, suggested that during growth in culture, the 18-81 cell line may undergo heavy-chain class switching; this is the process by which a clone of Blymphoid cells first expresses a single heavy-chain variable (V) region in association with μ heavy chains and subsequently with another heavy-chain class such as α or γ (ref. 8). The process often appears to be effected by a recombination/deletion mechanism. The order of the CH genes has been determined as $5'-(V_HJ_H)-C_{\mu}-C_{\delta}-C_{\gamma3}-C_{\gamma1}-C_{\gamma2b}-C_{\gamma2a}-C_{\epsilon}-C_{\alpha}-3'$ (ref. 9) so that, for example, expression of $\gamma 2b$ protein in a myeloma would result from juxtaposition of the C_{v2b} gene with the expressed V_HDJ_H complex by deletion of the intervening DNA sequence, including the C_{μ} , C_{δ} , $C_{\gamma 3}$, and $C_{\gamma 1}$ genes^{10,11}. Most of the evidence for the deletional model of heavy-chain class switching has come from comparative studies of heavy-chain gene structure in independently derived immunoglobulin-secreting myelomas⁹⁻¹⁶. Clearly, cloned cell lines such as 18-8, which undergo class-switching in culture, could be useful for elucidating this process. .

In addition, certain properties of 18-8 and its sublines suggest that these cells may be useful for generating variants having

^{*}Present address: Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York, New York 10027,

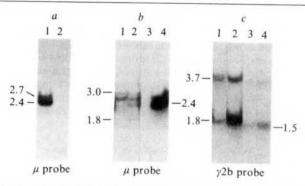

Fig. 1 Detection of μ and γ 2b RNA sequences in various 18-81 isolates. The derivation of the 18-8 line and its clonal derivative 18-81 has been described previously2. Subclones of 18-81 were derived by dilution and plating in microtitre wells at <1 cell per well. For LPS treatment, cells were plated at 4×10^5 cells ml⁻¹ and grown in the presence of $100 \,\mu g \, ml^{-1}$ Salmonella typhimurium LPS (Difco) for $48 \, h^{17,34}$. Parallel control cultures were evaluated in each experiment. To examine the RNA in the various 18-81 cultures, ~10 µg of total poly(A)-containing RNA prepared from the indicated sources was fractionated by electrophoresis through methylmercury hydroxide agarose gels, transferred to diazotized paper and hybridized with $\sim 10^7$ c.p.m. of a nick-translated cloned DNA probe for either μ sequences $(pAB\mu - 1)$ or $\gamma 2b$ sequences $(pAB\gamma 2b-1)$ (specific activity between 10^8 and 10^9 c.p.m. μg The pAB μ - 1 plasmid contains a 770-base pair (bp) μ cDNA and the pAB γ 2b-1 a 1,200-bp γ 2b cDNA insert⁴⁰. a, μ probe, RNA from: lane 1, young 18-81 culture; lane 2, 18-81A. b, μ probe, RNA from: lanes 1 and 2, 81A-2 cells; lanes 3 and 4, 81A-20 cells. Cells were either untreated (lanes 1 and 3) or treated with LPS (lanes 2 and 4). c, γ 2b probe: lanes as indicated for b.

altered regulation of immunoglobulin synthesis. During propagation of the 18-81 line in culture, its relatively high level of μ -chain synthesis (0.1% of soluble protein) decreases; after 9–12 months of culture it makes <10% of the μ chain found in the parent population 17 . The synthesis of μ chains in long-term cultures of 18-81 can be increased to a level approaching that of fresh cultures by treatment of the cells with bacterial LPS 17 . This suggests that growth of 18-8 cells in culture may select for variants having stable changes in the regulation of immunoglobulin heavy-chain gene expression. Such variants would be invaluable for studying the molecular basis of the various transitions in the level of heavy-chain gene expression that occur during B-cell differentiation.

Here we characterize cloned variants of the 18-8 line which exhibit one or both of the properties described above. The studies indicate that in these variants, heavy-chain class switching may occur without deletion of the C_μ gene and that the genetic alteration leading to decreased heavy-chain expression (and apparently the simultaneous acquisition of LPS inducibility of expression) is linked to DNA alterations near the functionally expressed $V_{\rm H}$ allele.

Loss of μ production during culture correlates with decreased levels of μ mRNA

To characterize the events involved in the decrease of μ protein synthesis in derivatives of cell line 18-8, we first analysed the relative level of μ -related RNA sequences in a line cloned soon after the establishment of 18-8 (called 18-81) and in the same line after 9 months of continuous passage (called 18-81A). Line 18-81 produced ~0.1% of its protein as μ chains; 18-81A had no detectable μ chains. For these analyses, total poly(A)-containing RNA was prepared, fractionated, transferred to diazotized paper and assayed for hybridization to 32 P-labelled μ -specific cloned DNA probes as described previously 18 . Hybridization with a probe specific for C_{μ} revealed a prominent 2.4-kilobase (kb) μ RNA, as well as a minor 2.7-kb species in the young culture (Fig. 1a, lane 1) but no detectable μ RNA in the long-term culture (Fig. 1a, lane 2). Hybridization with

sub-probes specific for $\mu_{\rm m}$ or $\mu_{\rm s}$ domains demonstrated that the 2.4- and 2.7-kb μ RNAs in the parent populations corresponded respectively to $\mu_{\rm s}$ and $\mu_{\rm m}$ RNA (ref. 18). Therefore, the decrease in μ protein production that occurred when the 18-81 line was grown in culture correlated with a reduction in μ mRNA accumulation.

Subclones of 18-81A produce either LPS-induced μ or γ 2b protein and mRNA

After ~9 months in culture the 18-81A line was subcloned to produce the 81A series of cell lines. Individual 81A lines were then examined for heavy-chain production by metabolic labelling and specific immunoprecipitation. Consistent with the behaviour of the parental line, of 40 81A lines examined, none constitutively synthesized significant levels of µ-related proteins. However, all but one of the lines synthesized μ protein after treatment with LPS; the behaviour of a representative line, 81A-20, is shown in Fig. 2, lanes 1 and 2. One line, 81A-2, produced no μ with or without LPS treatment but produced detectable levels of a y chain in the absence of LPS treatment (Fig. 2, lane 3) and greatly increased amounts after LPS treatment (Fig. 2, lane 4). Analyses using sera specific for various γ classes indicated that the γ produced by 81A-2 was γ 2b (not shown). This line also produced low levels of a μ -sized chain that was precipitated in our assay conditions (Fig. 2, lane 4), but which does not appear to represent μ protein because: (1) the precipitation of this protein occurred at variable levels; (2) it was observed with Staphylococcus aureus treatment alone; (3) it was not observed with double antibody precipitation; and (4) its precipitation was not competed with authentic μ protein (data not shown).

To ascertain that the γ -producing 81A-2 clone, the μ -producing 81A-20 clone and the 18-81 line were all sibling clones, we examined their integrated A-MuLV proviruses⁵. All the clones had identically integrated proviruses⁵, and must therefore have been descendents of the same, initially transformed cell because individual A-MuLV transformants have distinguishable proviruses¹⁹.

Analyses of the RNAs produced by the 81A lines yielded results parallel to those obtained by protein analyses. The μ -inducible, 81A-20 line contained a barely detectable level

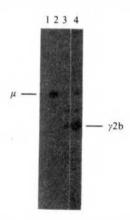

Fig. 2 LPS enhancement of μ and γ 2b production in various 18-81 isolates. Cell lines 81A-20 and 81A-2 were treated with LPS as described in Fig. 1 legend, then metabolically labelled with 35 S-methionine (80 μ Ci ml $^{-1}$) for 60 min as previously described 2,18,41,42 . Control cultures which did not receive LPS were incubated and labelled in parallel. Extracts were then prepared and incorporation into μ - or γ -related polypeptides determined by precipitation with rabbit anti-mouse immunoglobulin and SDS-polyacrylamide gel electrophoresis of the resulting precipitates as previously described 2,18,41,23 . Lane 1, 81A-20, no treatment; lane 2, 81A-20, LPS; lane 3, 81A-2, no treatment; lane 4, 81A-2, LPS. Identity of μ and γ chains was confirmed by specific immunoprecipitation and competition assays as previously described 18 .

of 2.4-kb μ_s mRNA which was greatly augmented by LPS treatment (Fig. 1b, lanes 3 and 4). A 1.5-kb γ -related RNA, the level of which was not significantly affected by LPS treatment, was also evident in this line when the same RNA was assayed using a γ 2b probe (Fig. 1c, lanes 3 and 4). This RNA species, however, does not appear to contain a V_H sequence (see Fig. 4) and is probably related to the 'sterile μ ' RNA transcripts described below.

The y2b-inducible 81A-2 line produced a diffuse pattern of μ RNA species ranging in size from 3.0 to 1.8 kb and the abundance of these species was not affected by LPS (Fig. 1b, lanes 1 and 2). These 'sterile μ ' RNA sequences²⁰, which are probably related to those described by others21, are found in many A-MuLV-transformed cell lines and do not encode µ chains²⁰. The 81A-2 line also contained 1.8- and 3.7-kb species of y-related RNA (Fig. 1c, lane 1); the level of the 1.8-kb species was greatly augmented by LPS treatment (Fig. 1c, lane 2). Characterization of these RNAs with DNA probes specific for the various v subclasses confirmed their identity as mRNAs for the membrane-bound (3.7 kb) and secreted (1.8 kb) forms of γ 2b protein^{22,23}. Thus, as observed by analyses of both protein and RNA, clone 81A-2 has apparently stably shifted from μ to $\gamma 2b$ production in culture. In addition, like μ expression in the parental line or sibling clones, γ 2b expression is low in 81A-2 but inducible to high levels by treatment of the cells with LPS.

Heavy-chain gene rearrangements in the 18-8 series

To examine whether the switch to γ 2b production in 81A-2 was paralleled by changes in the cell DNA, we performed a

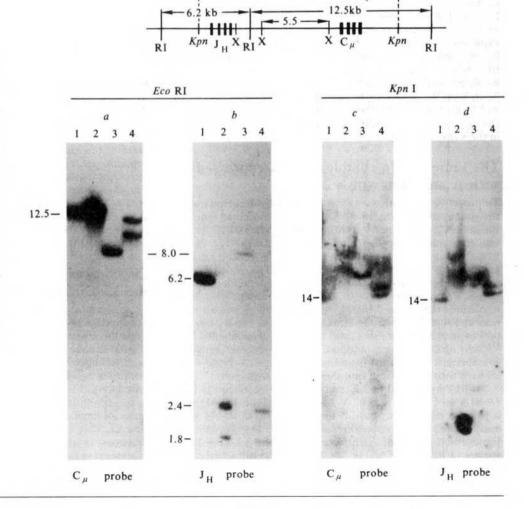

restriction endonuclease analysis of the C_μ and J_H regions in the DNA of 81A-20 and 81A-2. In the germ line of the BALB/c mouse, all the C_μ exons occur on a single EcoRI fragment of 12.5 kb, called here the RI- C_μ fragment, and the J_H segments are located on a contiguous 6.2-kb EcoRI fragment, called here the RI- J_H fragment (Fig. 3). Any rearrangement in which a V_H or D_H region is abutted to a J_H should abolish the germ-line RI- J_H fragment and generate a new fragment containing the DNA sequence lying between the active J_H and the nearest 3' EcoRI site.

To assay the DNA segments in various cell lines, DNA was prepared, digested with EcoRI and assayed for hybridization to ^{32}P -labelled DNA probes representing either the RI-J_H fragment⁵ or the C_{μ} region 18 . As observed with embryo DNA (Fig. 3a, lane 1), a major, 12.5-kb EcoRI fragment in the DNA of the 18-8 parental line hybridized to the C_{μ} probe (Fig. 3a, lane 2). When assayed with the RI-J_H probe, however, two fragments of \sim 2.4 and 1.8 kb were observed in the parental 18-8 line (Fig. 3b, lane 2), neither of which corresponded to the unrearranged 6.2-kb fragment observed in DNA from mouse embryo (Fig. 3b, lane 1). This result indicates that both $J_{\rm H}$ alleles had undergone rearrangement in the 18-8 line and was confirmed by demonstrating that the 1.6-kb EcoRI fragment directly 5' to the RI-J_H fragment in embryonic DNA was absent from the genome of 18-8 and its daughter lines⁴.

In the DNA of the 18-81A line, only a single EcoRI fragment of 8.0 kb hybridized to the C_{μ} probe (Fig. 3a, lane3). In addition, this cell population contained only a single observable RI-J_H fragment which was identical in size (8.0 kb) to that containing the C_{μ} gene (Fig. 3b, lane 3); this was confirmed by eluting the RI-J_H probe and rehybridizing with the C_{μ} probe (data not shown). These results imply that one J_{H} - C_{μ} allele had been lost

14 kb

Fig. 3 Analysis of heavy-chain gene rearrangements in various 18-8 isolates. Upper part, restriction map of J_H-C_{\(\mu\)} region. Relevant EcoRI (RI), KpnI (Kpn) and XbaI (X) sites are indicated. Lower part, approximately 10 µg of cel-DNA indicated from sources were digested with EcoRI (panels a, b) or KpnI (panels c, d) and assayed by DNA blotting procedures for hybridization to the 32P-labelled (final specific activity = 10^8 - 10^9 c.p.m. μ g pAB μ – 1, C_{μ} probe (panels a, c) or the pRI-J_H, J_H probe (panels b, d) as described elsewhere4. Plasmid pAB μ - 1 is described in Fig. 1 legend; pRI-J_H has a 6.2-kb insert which corresponds to the embryonic EcoRI fragment containing the JH segments (see map above). Lane 1, BALB/c embryo DNA; lane 2, 18-8 DNA; lane 3, 18-81A DNA; lane 4, 81A-2 DNA.

in the 18-81A population whereas the other had undergone a deletion of \sim 5-6 kb spanning the EcoRI site between RI-J_H and RI-C_m.

The location of the deletion in the single J_H - C_μ region in line 18-81A was also confirmed by hybridization with sub-probes specific for this intron region (see below) and by cleavage analyses with other enzymes. An identical 8.0-kb fragment hybridizing to both the RI- C_μ and RI- J_H probes was also observed in the DNA of 81A-20, the μ -inducible clone (data not shown), implying that the heavy-chain allele containing the large deletion—the only one present—is the one expressed in this and therefore the other 18-8 related lines. In addition, a loss of one C_μ allele and a deletion in the other occurred when a separate population of 18-81 was maintained in culture until μ -gene expression substantially decreased (data not shown).

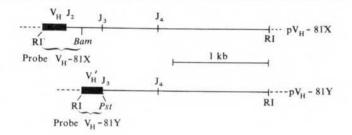

Analysis of the RI-J_H region in the DNA of the $\gamma 2$ b-producing derivative, 81A-2, indicated the presence of RI-J_H regions originating from both chromosomes and showed no evidence of rearrangement with respect to the configuration found in the 18-8 ancestral line (that is, 2.4- and 1.8-kb fragments; Fig. 3b, lane 4). In addition, two RI-C_{μ} fragments of 11.0 and 9.5 kb were found in the DNA of this line (Fig. 3a, lane 4). This result suggested that the shift to $\gamma 2$ b production in 81A-2 may have occurred without deletion of a C_{μ} gene.

To examine further whether 81A-2 retained both C_µ alleles, we analysed the J_{H} - and C_{μ} -containing fragments generated when the DNA of this line was digested with KpnI. Figure 3 shows that KpnI cuts 3' to the C, exons and 5' to the JH segments, thus generating a single 14-kb embryonic DNA fragment containing both these regions. Rearranged genes, in which the C., regions are still associated with the JH region, should result in identical patterns of hybridization when KpnI-digested DNA is assayed with either RI-J_H or C_µ probes. Juxtaposition of the JH region to a y2b allele, however, might be expected to produce a unique KpnI fragment when assayed with RI-JH. As predicted, C_μ and RI-J_H probes showed identical patterns of hybridization to a 14-kb KpnI fragment of embryonic DNA (Fig. 3c, d, lanes 1) (the C_u-containing fragment was more distinct in other experiments). In DNA from line 18-8, both probes hybridized to 18.5- and 17-kb fragments (Fig. 3c, d, lanes 2). In DNA from 81A-20, the probes located only a single 17-kb fragment, consistent with the presence of only one JH-C region (Fig. 3c, d, lanes 3). In DNA from line 81A-2, two fragments of 16 and 15 kb hybridized to both probes (Fig. 3c, d, lanes 4), suggesting that both J_H alleles were still associated with C_µ genes in the y2b-producing line.

The same V_H - J_H complex is first expressed with μ and then with $\gamma 2b$

To prove rigorously that a switch had actually occurred during the propagation of the 18-81 cell line, we examined whether the same $V_{\rm H}$ gene expressed with C_{μ} in the parental 18-81 line was subsequently expressed in association with $C_{\nu 2b}$ in the 81A-2 subclone. We molecularly cloned both RI-J_H fragments from 81A-2 into λ phage Charon 16A and demonstrated by nucleic acid sequencing that they contained independently rearranged $V_{\rm H}$ genes rearranged to $J_{\rm H}2$ ($V_{\rm H}$ -81X) and $J_{\rm H}3$ ($V_{\rm H}$ -81Y) (structures summarized in Fig. 4; data to be presented elsewhere). From these two clones we prepared the two $V_{\rm H}$ -specific probes as indicated in Fig. 4, and these were then labelled with ^{32}P by nick-translation and used to probe total poly(A)-containing RNA isolated from lines 18-81A, 81A-2 and 81A-20 both with and without (not shown) LPS treatment.

 V_H -81Y hybridized to 2.7- and 2.4-kb RNA species in both 18-81A (not shown) and 81A-20 RNA (Fig. 4a, lane 1) with a pattern identical to that obtained when these RNAs were assayed with a C_μ probe (Fig. 1a, lane 1; Fig. 1b, lane 4). Furthermore, this probe hybridized to 1.8- and 3.7-kb γ RNA species in 81A-2 RNA (Fig. 4a, lane 2), a result identical to that obtained when this RNA sample was assayed with a γ 2b probe (Fig. 1c, lane 2). The V_H -81X probe did not hybridize

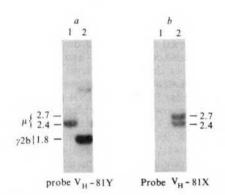

Fig. 4 Upper part, partial restriction map of clones pVH-81X and pV_H-81Y. The plasmids pV_H-81X and pV_H-81Y have, respectively, 2.4- and 1.8-kb inserts containing the rearranged V_HJ_H complexes from 81A-2 as indicated in the map. The plasmids were derived by subcloning the inserts from EcoRI-digested Charon 16A genomic clones into the EcoRI site of pBR322. All procedures conformed to the NIH guidelines for recombinant DNA research. The probes V_H-81X and V_H-81Y were prepared by dissecting the indicated restriction fragments from each clone and then purifying these by agarose gel electrophoresis and labelling with 32P by nick-translation as previously described 18. Lower part, expression of rearranged VH genes in 18-81 clones. Approximately 10 µg of poly(A)-containing RNA from 81A-20 (lane 1) and 81A-2 (lane 2) were fractionated by methylmercury hydroxide agarose gel electrophoresis, transferred to diazotized paper and assayed for hybridization to probe V_H-81Y (a) or V_H-81X (b).

to any RNA in 81A-20 cells (Fig. 4b, lane 1), consistent with the loss of this allele from the cell line (see above). This probe did, however, hybridize to a 2.7- and 2.4-kb $\mu_{\rm m}$ - and $\mu_{\rm s}$ -sized RNA doublet in 81A-2 RNA (Fig. 4b, lane 2) but these sequences apparently result from a non-productive rearrangement at the unexpressed allele and do not encode normal μ proteins (see ref. 20). These results confirm that the 81A-2 clone has undergone a class switch from μ to $\gamma 2$ b production using the same rearranged $V_{\rm H}$ -J $_{\rm H}$ region to make both types of RNA. Furthermore, in all these lines, only the RNA sequences hybridizing to the $V_{\rm H}$ -81Y probe showed a significant response to LPS treatment, suggesting that LPS sensitivity was a property of the expressed allele.

Derivatives of 18-8 accumulate deletions in the J_H-C_μ intron during growth in culture

To analyse further the deletions which occurred near the C_{μ} gene in the 18-8 cell lines, we prepared a 32 P-labelled probe from the major XbaI fragment lying within the J_H - C_{μ} intron (Fig. 3) and used it to analyse the size of homologous fragments in XbaI-digested DNA from the various lines. As expected, this probe labelled a prominent 5.5-kb XbaI fragment in embryonic DNA (Fig. 5, lane 1). In DNA from the 18-8 line, the intron probe labelled both the 5.5-kb fragment as well as a series of smaller fragments ranging in size to <3 kb (Fig. 5, lane 2). This suggested that the 18-8 line was accumulating deletions in this region during growth in culture. Similar analyses revealed no size heterogeneity of restriction fragments representing sequences lying 5' or 3' to those represented by the intron probe (data not shown), supporting the proposal that

sequences within the region covered by the probe have a predisposition for deletion, as suggested by others2

Additional support for the suggestion that 18-8 accumulated J_H-C₄ deletions during culture was provided by the observation that DNA from the 81A-20 and 81A-2 clones did not contain XbaI fragments of embryonic size that hybridized with the intron probe (Fig. 5, lanes 3 and 4). Although both Cu alleles appeared to be present in the 81A-2 line, the XbaI-digested DNA from this line contained only one obvious fragment of ~2.3 kb which hybridized to the intron probe (Fig. 5, lane 3). Analyses using other enzymes and probes indicated that the lack of a second hybridizing fragment probably resulted from a deletion in the second allele which removed most of the sequence homologous to the probe (data not shown), a result consistent with the small size (9.0 kb) of one of the Cucontaining EcoRI fragments in this line (Fig. 3a, lane 4). Similarly, from other experiments, the large size (5 kb) and weak hybridization of the single hybridizing XbaI fragment in 81A-20 DNA (Fig. 5, lane 4) seems to have resulted from a large deletion removing the first two XbaI sites directly 3' to the JH segments (Fig. 3), the 5' XbaI site now being provided by sequence associated with the rearranged VH gene.

Mechanism of switching

Previous evidence has suggested that cells producing μ chains can switch to production of other heavy-chain isotypes^{8,25,3} but only in the case of cells that have activated δ synthesis has evidence been provided that the same VH region is expressed first with μ and then with the derivative heavy chain²⁷. The present report shows that an A-MuLV transformant which has switched from μ to γ 2b synthesis, uses for its γ 2b protein what appears to be the same VH region as used by the parental line for its μ protein. The apparent identity of the V_H regions used

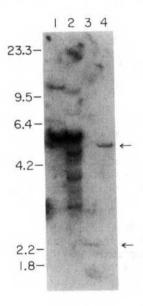

Fig. 5 Deletions within the J_H - C_μ intron. The J_H - C_μ intron probe was prepared by dissecting the 3.5-kb XbaI fragment corresponding to the major 5.5-kb XbaI fragment in the JH-C, intron (see Fig. 3) from a genomic clone (pRI-C_µ) which has a 10.5-kb insert containing the C_µ gene⁴. The insert of this plasmid corresponds to the embryonic 12.5-kb EcoRI fragment which contains the C₄ exons (see Fig. 3) but during cloning has undergone a ~2-kb deletion several kb 5' to the first C_{\(\mu\)} exon. The size of the excised XbaI fragment (3.5 kb) was a result of this deletion. Approximately 10 µg of DNA from the indicated sources were digested with XbaI, fractionated by electrophoresis through 1% agarose gels, transferred to nitrocellulose paper and assayed for hybridization to the J_H – C_μ intron probe labelled with ^{32}P by nick-translation. DNA from: lane 1, BALB/c embryo DNA; lane 2, 18-8; lane 3, 81A-2; lane 4, 81A-20.

in the μ and γ 2b proteins is indicated by the following: the VH genes joined to the JH regions on the two chromosomes in 18-8 cells and its derivatives have been molecularly cloned and are denoted V_H -81X and V_H -81Y; a μ -producing 18-8 derivative has lost one allele but retained V_H-81Y in its μ mRNA, identifying this as the V_H that encodes the μ protein; the $\gamma 2b$ mRNA in the γ 2b-producing derivative hybridized to V_H-81Y but not V_H-81X, identifying V_H-81Y as the V_H region that encodes the γ 2b protein and showing that the μ and γ 2b proteins share VH regions. Actually, the identity of VH regions on the two mRNAs was established mainly by cross-hybridization, but based on the lineage relationships of these lines, the possibility that the cross-hybridizing V_H regions are not identical is very low.

The mechanism of heavy-chain switching has previously been inferred from observations on the configuration of the heavychain genes in myeloma cells, tumour cells that represent terminally differentiated cells of the B-lymphoid lineage. These studies have indicated that class switching occurs by a deletional mechanism9-16, and this process is apparently mediated by switch recombination sites, a set of which lies 5' to each of the C_H genes^{15,16,28,29}. Thus we expected that the switch of 18-81 cells from μ synthesis to γ 2b synthesis would be accompanied by a deletion of at least one copy of the C, gene segment in these cells. However, the y-producing 81-A2 line described here retains two copies of the C_{μ} gene, each of which still appears to be associated with the V_H complex (Fig. 3). Because digests using other enzymes suggest the possibility of an alteration within or near the C_µ gene on one of the alleles (F.W.A. and D.B., unpublished results), additional molecular cloning analyses will be necessary to confirm the linkage. However, analysis of the γ 2b gene in these lines using a series of different restriction endonucleases revealed no obvious alterations near either the y2b gene or its flanking sequences (data not shown). In addition, there are examples of at least two other A-MuLVtransformed lines that apparently have undergone a switch to γ production without loss of a C_{μ} gene (see ref. 20). The data available imply that the switch to $\gamma 2b$ production in A-MuLV transformants results from transcription through the C, gene, with deletion of the C_µ and other intervening sequences occurring by a post-transcriptional processing mechanism. Such a mechanism would be analogous to that proposed as mediating the transition from μ_m to μ_s RNA production 18,30,31 and the simultaneous expression of μ and δ genes by the same cell^{27,32,33}, and predicts either a very long (>50 kb) primary transcript or a rearrangement placing the y2b gene closer to μ , perhaps in the place of δ . Whatever the mechanism, this line should provide an excellent model system for studying various aspects of the class-switching process.

It has been suggested that the occurrence of class switching in 18-81 cells demonstrates that pre-B lymphocytes can carry out the class switch event7. Although it is true that most A-MuLV-transformed cells appear closely related to pre-B lymphocytes, 18-81 may be an exception; as opposed to most other A-MuLV transformants, it gives rise to subclones having rearranged κ light-chain genes^{4,5} some of which produce κ protein^{6,34}, it makes predominantly the secreted form of μ mRNA (Fig. 1), and it probably produces a low amount of J chain (M. Koshland, personal communication). These characteristics suggest that 18-81 is a cell line having a propensity to mature beyond the pre-B-lymphoid cell stage. Thus, the relatively high frequency of γ-producing cells generated by this line may be a consequence of its maturational potential as opposed to an event of the pre-B lymphocyte.

Class switching in cultured cells

Other laboratories have been able to detect among cultured myeloma and hybridoma cells, variants that express a new heavy-chain isotype³⁵⁻³⁷. In these experiments, powerful mutagenic and selective methods were used to recover the very rare class-switch variants which appear in non-mutagenized

cells at a frequency of <10⁻⁶ per cell per generation^{36,37}. Our analyses, together with those of Burrows et al.⁷, suggest that μ to $\sqrt{2}$ b class switching is continually occurring in the 18-8 cell line and in some isolates may occur at a frequency as high as 10⁻² per cell per generation.

A second difference between the selected myeloma and hybridoma variants and A-MuLV transformants is that the 81A-2 line has switched from μ to γ 2b expression, skipping the intervening $\gamma 3$ and $\gamma 1$ C_H regions, whereas the selected variants generally switch to a neighbouring C_H gene³⁵⁻³⁷. The switch from μ to a different heavy-chain isotype is thought to occur normally during B-cell differentiation. Switching from one γ subclass to a different subclass—as occurs in the myeloma variants—has not been reported for normal B cells and the significance of this type of low-frequency switching in permanent cell lines is not clear. A μ to δ class-switch variant has been described³⁷ and probably results from deletion of the C_n gene²⁷.

Regulation of μ expression

The high level of μ -specific protein and RNA expressed by the 18-8 and 18-81 A-MuLV-transformed cell lines (0.1% of soluble protein; see ref. 2) is relatively unique among μ -positive, light chain-negative A-MuLV-transformants, which generally produce ~10-fold lower levels. Previous studies have demonstrated that the production of high levels of heavy chains has an adverse effect on the growth of plasmacytoma lines that have lost light-chain gene expression³⁸. In view of this result, the decline of μ production in long-term cultures of the μ -only 18-8 lines most probably results from the selective outgrowth of cells in which μ production has decreased, while the relative stability of μ levels in many μ -only A-MuLV-transformed lines (N.R. and F.W.A., unpublished results) may reflect the low levels of the protein produced initially.

The decreased μ production in various 18-81 isolates is usually inducible to the original high levels on treatment of the cultures with LPS. We have as yet little information on the genetic basis of the decreased expression or induction phenomena. However, note that in the 81A-2 clone that has switched to γ 2b production, γ 2b protein and RNA sequences show an extent of LPS induction similar to that observed for μ sequences in the parental line whereas the defective μ mRNA sequences produced from the second allele show little or no induction (Fig. 1). This result suggests that the structure mediating the induction is associated with the expressed V_H gene or its flanking sequences and is presumably an element of DNA structure. In this regard it is significant that in the two low-level μ producers that are LPS-inducible, only a single copy of the μ gene was apparent, and this had undergone an extensive deletion in the intron between J_H and C_u. An intriguing possibility is that a sequence in the deleted region has a positive involvement with μ production and that loss of that sequence can be overcome by LPS treatment. It should be noted, however, that deletions within this region of up to 2.8 kb are compatible with high-level μ production in myelomas³⁹.

The deletions that occur within the J_H-C_{\(\mu\)} intron during propagation of the 18-8 line may be related to strain-associated length variations in that region²⁴ as well as to deletions within that region which are observed in myelomas and which occur

when C_{μ} genes are cloned and propagated in *Escherichia coli*^{15,16,24,28}. The latter two phenomena have been ascribed to a propensity of the S_u region—which lies ~2 kb 5' to the C_u gene—to promote deletions 15,16,24,28. Although many of the deletions within this region observed in the 18-8 populations may be analogous in size to those described for myelomas or molecular clones (~2 kb), the deletions observed in some of the 81A clones are much larger (>5 kb). However, these deletions do appear to have their 3' termini near the S_u region. Whether or not all these deletions are also mediated by the S_u region remains to be determined. However, an intriguing possibility is that the high rate of deletion within this region is related to the propensity of the 18-8 line to undergo class switching. Most A-MuLV-transformed lines have deletions within this region (not shown) and the only other line examined in detail, 300-18, also accumulated these deletions during the growth in culture (F.W.A. and D.B., unpublished observations). However, of five permanent T-cell lines examined, all of which had been in long-term culture, none showed evidence of deletions within this region, suggesting that the activity responsible may be B-cell specific.

Conclusion

These data emphasize the variety of phenotypes to be found among the many cell lines transformed by A-MuLV. In this case, subclones from a single transformant, 18-81, have shown a switch from μ to γ 2b synthesis and a progressive loss of heavy-chain gene expression. Analysis of both events has uncovered aspects that may be important to the general understanding of immunodifferentiation.

The switch from synthesis of μ to synthesis of γ 2b was accomplished without the expected loss of a C, gene, which suggests that class switching beyond the δ gene may be, at least partly, a transcriptionally controlled event in contrast to previous evidence for a deletional mechanism⁹⁻¹⁶. Deletion certainly occurs, but it may be secondary to a transcriptional (or RNA processing) switch. The progressive loss of heavy-chain synthesis has two interesting aspects: it can be reversed by LPS treatment of cells and can be correlated with deletion in the J_H-C_u intron. Although the causative relationships have not been proved, the results suggest that transcription of heavychain genes (both μ and γ 2b) or the processing of initial transcripts may be regulated by DNA sequences in the J_H-C_u intron. Both the amount of mRNA produced and the control of mRNA levels by LPS were correlated to the deletion; if these measurements reflect transcriptional activity, immunoglobulin gene expression may be regulated by DNA elements in the J_H-C_u intron rather than any upstream of the V_HJ_HC_H complex. This is a reasonable assumption because otherwise each V_H gene would be required to carry a complete regulatory region 5' to its structural gene. The way in which elements of the intron may regulate transcription requires further study.

The nuclei of Sevfert galaxies contain very turbulent motion and are often intense sources of radio emission. It has been proposed that very compact supermassive objects could be the source of these energetic phenomena. Speckle observations of the nucleus of NGC1068 have revealed for the first time the presence of such an object with a diameter of ≤2.3 pc but emitting an amount of visible light equivalent to that from 5×10^9 solar masses.

NGC1068 is an Sb spiral galaxy1 with a Seyfert nucleus2 which is at distance³ of 16 Mpc (assuming H_0 = 75 km s⁻¹ Mpc⁻¹). Several observers³⁻⁶ have studied the broad (≈1,450 km s⁻¹) [O III] emission lines from the central (=300 pc diameter) regions. There are at least four distinct clouds with separate velocities within this range and the total kinetic energy³ in this turbulent ionized gas is $\approx 9 \times 10^{54}$ erg. Bertola⁶ has detected a stellar-like inner nucleus with a diameter of $\leq 160 \,\mathrm{pc} \,(\leq 2 \,\mathrm{arc}\,\mathrm{s})$ which emits 9% ($\simeq 12 M_{\rm v}$) of the total visible continuum of the galaxy. The variability of this optical emission has suggested that this may originate within a volume as small as a few light months.

High-resolution (=1 arc s) radio observations of the nuclear regions of NGC1068 by the Jodrell Bank MERLIN array8 and VLA9 reveal that an intense source of non-thermal radio emission of \approx 77 pc diameter (\approx 1 arcs) is coincident with this central object. This is of size comparable with the upper limit of the 10 µm IR structure¹⁰, whereas radio VLBI measurements^{11,12} have, so far, failed to detect emission on an angular scale of ≥ 0.1 arc s.

Speckle observations of the optical continuum emission from the central active nucleus of NGC1068 permit its angular structure from 0.03 to 0.9 arcs (2.3 to 70 pc) to be investigated. The nucleus of NGC1068 was observed with the Imperial

College of Science and Technology (London) speckle interferometer¹³⁻¹⁷ combined with the f/15 focus of the 3.9 m Anglo-Australian Telescope.

This device has an EMI, four-stage, image tube (\$20) combined with a Plumbicon TV camera and detects individual photon events, (with the combination of lenses used for NGC1068) over the image of a 3.07 arcs square ($=256 \times 256$ pixels) field. An individual recording is obtained, with an exposure time of 1/50 s, of this atmospherically distorted image which is then auto-correlated on-line within 1/25 s. Over an extended observing period these separate, two-dimensional auto-correlations are co-added and finally an auto-correlation is obtained for the 3.07 arc s² area in which objects separated by ≤ 0.9 arc s and ≥ 0.03 arc s (the limiting angular resolution of the telescope at 5,000 Å for instance) are capable of being detected. This is stored on tape in an array from -64 to +63pixels in the x dimension (right ascension) and from 0 to -63pixels in the -y dimension (declination) where the 00 pixel is the zero of the two-dimensional auto-correlation and is the centre of the narrow 'photon spike'.

The integrated auto-correlation of the field, which contains the object under investigation, is then compared with that for a star, known to be single, near in angular distance to the object and of nearly equal brightness (a neutral density filter can be used). If the observations of this reference star are made immediately after those on the object, for the same integration time and through the same filter then it can reasonably be assumed that the statistical properties of the turbulence in the atmosphere are similar in both cases and a significant comparison of the auto-correlations can be made.

The observations of the nucleus of NGC 1086 with this system are summarized in Table 1. (The 5,007 Å emission line was shown to be negligibly faint in a separate integration through a narrow filter.) Figure 1 shows a grey-scale representation (using the Manchester node of the STARLINK network) of the two-dimensional auto-correlation obtained for NGC1068 and emphasizes the very faint features (D-E) which are produced by separate sources within the 3.07 arc s² area that is auto-correlated but which are ≥200 times fainter than the single dominant source. This is primarily responsible for the intense and narrow central feature (around the 00 pixel), which is 'burnt out' in Fig. 1. However, in Fig. 2 the cut in the y direction through this central feature, from the 00 pixel, is compared with the same cut through the auto-correlation for the reference star (see Table 1). This was scaled to give the same number of counts in the photon spike around (the 00 pixel) as that obtained for NCC1068.

	Tal	ble 1 Speckle observations of	NGC1068 and refere	nce star	
Object	Field size (arc s)	Field centre (1950)	Filter (Å)	Integration time (s)	No. of separate frames autocorrelated
Nucleus NGC1068	3.07×3.07	$\alpha = 2 \text{ h } 40 \text{ m in } 07.1 \text{ s}$ $\delta = 00^{\circ}13'31.4''$	5,000-5,600	1,160	2.89×10^4
Ref. Star $(M_v = 9.0)$	3.07×3.07	$\alpha = 2 \text{ h } 41 \text{ m in } 11.33 \text{ s}$ $\delta = 00^{\circ}0'2.3''$	5,000-5,600 (ND = 1.0)	850	2.125×10^4

Table 2 Sources in the auto-correlation of NGC1068

Source	$M_{ m v}$	Separation from primary (arc s)	Separation from primary (pc)
Α	11.8 ± 0.3	0	0
В	17.7 ± 0.05	0.51 ± 0.03	40
C	19.0 ± 0.05	0.27 ± 0.03	21
D	18.2 ± 0.05	0.47 ± 0.03	37
E	17.4 ± 0.05	0.60 ± 0.03	47

The auto-correlation displayed in Fig. 1, and the cut through this and the reference star in Fig. 2, demonstrate that the nucleus of NGC1068 is dominated by a stellar-like object (source A) which is unresolved by the 0.03 arc s resolution of this system (this is a conservative upper limit to this diameter). A comparison of the counts in this central region of the auto-correlation with those obtained for the reference star give a value for source A of $M_v \approx 11.8$, which is very similar to the magnitude of the continuum emission from the entire central ≤160 pc as estimated from the work of Burbidge et al.3 and Bertola6. This suggests that most (see Table 2 and Fig. 1) of this nuclear emission originates within a region of ≤0.03 arcs diameter (≤ 2.3 pc) with a luminosity of $\simeq 5 \times 10^9 L_{\odot}$.

Several possibilities for the nature of this dominant compact source should be considered. For example, the optical emission could be intense synchrotron radiation, though the failure to detect this object using radio VLBI techniques (angular resolution of ≤0.1 arcs) could be explained by synchrotron selfabsorbtion with a turnover frequency of $\approx 10^{10}$ Hz (this implies an angular size of $\leq 10^{-4}$ arc s). Also thermal free-free absorption could be occurring in front of the source and an emission measure of only 108-109 pc cm⁻⁶ would be required to make a central synchrotron radio source not observable. However, the discovery of optical circular polarization¹⁸ argues against the synchrotron hypothesis.

Alternatively, this central source could be an extremely compact star cluster with a total mass of $\approx 5 \times 10^9 M_{\odot}$ and a mass density of $\ge 8 \times 10^8 \, M_{\odot} \, \mathrm{pc}^{-3}$ if a simplistic mass-to-luminosity relationship is applied. If this is dynamically bound then a velocity dispersion of $\ge 5 \times 10^3$ km s⁻¹ would be required which is in excess of the observed widths of the stellar absorption lines. Also, variability of the optical continuum cannot occur in the integrated light from such a large number of separate

A more likely possibility is that the compact dominant source A is a supermassive, single, condensed object comparable to that inferred to be at the centre of M87¹⁹. The existence of radio jets in Seyfert nuclei^{8,20} has been interpreted on the basis of beams emitted along the rotation axis of such objects.

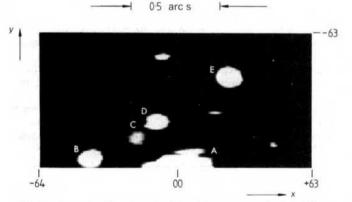

Fig. 1 A grey-scale representation of the auto-correlation of the nucleus of NGC1068. The central source A around the 00 photon spike is 'burnt out' here to permit the fainter (≥200 times) secondary sources B-E to be revealed. Other minor features are thought to be noise or cross-correlations. The irregularities around the primary A are also on the noise level and not thought to be real.

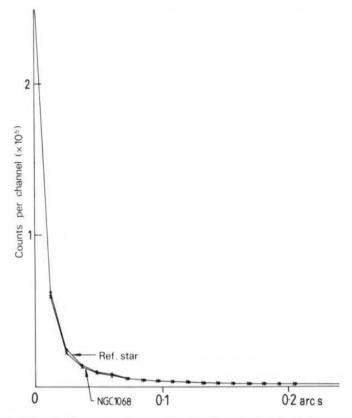

Fig. 2 The cut in the -y direction through the 00 pixel for NGC1068 in Fig. 1 is compared with the corresponding cut through the auto-correlation of the point reference star.

The secondary maxima B-E in Fig. 1 could be produced by four much fainter sources with the magnitudes and separations from the primary that are listed in Table 2. Similar features do not appear on the auto-correlation of the reference star and they are thought most probably to originate within the nucleus of NGC1068 and not be caused by faint foreground stars in our Galaxy.

However, caution is required in the interpretation of the configuration in Fig. 1 for cross-correlations between these secondary sources could also appear as secondary maxima and until some detailed modelling is carried out (which will also consider orientations of the secondary sources) it can only be stated that certainly two but possibly up to four secondary, unresolved, sources are clustered around the primary compact object in the nucleus of NGC1068. Even their nature could be unusual and require similar, but less dramatic, explanations to those for the primary source.

J.M. and H.V. thank the staff at the Anglo-Australian Telescope in November 1981, when these observations were made. This work has been supported by the SERC and in particular J.M. is grateful for his SERC Senior Fellowship.

A CCD image of the galactic centre

J. W. V. Storey & J. O. Straede

Anglo-Australian Observatory, PO Box 296, Epping, New South Wales 2121, Australia

P. R. Jorden, D. J. Thorne & J. V. Wall

Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, East Sussex BN27 1RP, UK

Because the galactic centre lies behind approximately 27 magnitudes of visual extinction, observations at visible wavelengths are impossible. The recent introduction of charge-coupled devices (CCDs) to astronomy represents the first opportunity to use sensitive area detectors in the near IR. Using a cooled CCD, we have obtained an image of the galactic centre at an effective wavelength of 0.9 µm. Two unresolved sources were found, separated by 3 arc s along the galactic plane. The detection of the two sources was confirmed by a further observation the following night. The possibility that the new sources are foreground objects cannot be completely ruled out; however, their positions are remarkably close to those of the non-thermal radio source and the 2.2 µm source IRS-16. While it is possible that the new sources could be a pair of highly reddened individual stars or compact clusters, it seems more likely that they are two compact H II regions seen in line emission.

The CCD image (Fig. 1) was taken at the prime focus of the Anglo-Australian Telescope (AAT) on 8 September 1981 during conditions of sub-arcsecond seeing. The CCD camera was built for the Anglo-Australian Observatory (AAO) by the Royal Greenwich Observatory, and uses as a detector an RCA SID 53612 chip with 320×512 pixels, giving an image scale of 0.50 arcs per pixel. The exposure time was 10 min through an RG830 (8,300 Å long-pass) filter. Although the far-red response of the CCD is not well known, the quantum efficiency is believed to fall linearly from about 60% at ~8,000 Å to zero at 10,500 Å, thus defining with the RG830 filter an effective bandpass of ~1,000 Å centred on 9,000 Å. The image has been flat-fielded by division by an exposure of blank sky-this process is necessary to remove interference fringes which are generated in the detector chip by strong night-sky emission lines.

Comparison of Fig. 1 with a IV N Schmidt plate (courtesy of the UK Schmidt Telescope Unit) allows all the stellar images to be identified with previously known stars except for the two images marked CCD1 and CCD2. The two new sources must therefore be highly reddened as would be expected for sources in the galactic plane at the distance of the galactic centre.

In the absence of spectroscopic data one cannot completely rule out the possibility that the new sources are foreground objects which appear in line with the galactic centre purely by chance. This would require a remarkable coincidence, however, as their positions are very close to those of the non-thermal radio source and the 2.2 µm source IRS-16, which are normally assumed to mark the galactic centre. No other very red objects are prominent on the CCD frame. In addition, Allen, Carter and Malin (personal communication) have made a partial map with 2 arc s resolution of the immediate vicinity of these objects in Brackett y and find two corresponding peaks in the line intensity. Although Brackett y emission is present in Be stars, the probability of finding two such stars of almost identical magnitude within 3 arc s of a given point is infinitesimal.

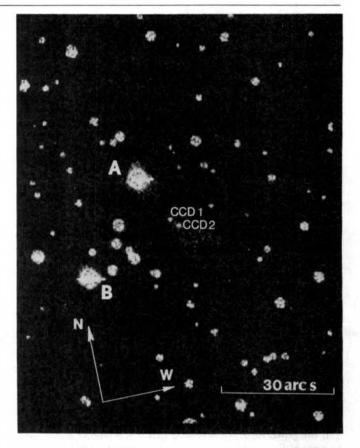

Fig. 1 CCD photograph of the galactic centre at an effective wavelength of 0.9 µm. All the stellar images are also seen on a IV N plate, with the exception of those marked CCD1 and CCD2. The bright stars identified as A and B are field stars used for positional information.

Positions for the new sources were obtained by measurement relative to two brighter visible field stars, shown as A and B on Fig. 1. These stars were in turn identified on the Palomar Sky Survey E plate and their positions determined relative to 15 nearby Smithsonian Astrophysical Observatory stars by measurement of the plate on a microdensitometer, followed by a six-parameter least-squares fit. The positions of all four stars are listed in Table 1, and should be accurate to better than 1 arc s. Star A is the visible star identified on the 2.2-μm map of Becklin and Neugebauer1; the position they determined agrees with the present value to within 0.8 arc s in each coordinate.

The intensities of the new galactic centre sources were determined by calibration against the white dwarf LDS749B, whose magnitude at 9,000 Å can be derived from the work of Oke². The resulting values are 18.9 ± 0.5 for CCD1 and 19.1 ± 0.5 for CCD2. This is equivalent to an observed flux of 1.9× $10^{-21}\,\mathrm{W\,cm^{-2}}$ from each source, corresponding to a dereddened flux of $2.2\times10^{-16}\,\mathrm{W\,cm^{-2}}$ for a visible extinction of $A_{\rm V}$ = 27 mag (ref. 3) and assuming the extinction follows Van de Hulst's curve number 15 (ref. 4).

The galactic centre has previously been detected at 1.06 and 1.18 µm using a 22 arcs aperture5. The observed magnitudes were 13.9 and 12.4 respectively. Comparison with the present result suggests that most of the flux seen by Spinrad et al.5 must have come from extended emission. There is some indication of nebulosity on the CCD frame, but its reality requires confirmation.

The shortest IR wavelength map available is that by Becklin and Neugebauer¹ at 2.2 µm. In this map, the central source (IRS-16) is seen to be slightly extended. The resolution used (2.5 arc s) is not sufficient to indicate whether the images seen by the CCD are also visible at 2.2 µm; however; they clearly are not prominent. In an early radio work at high resolution

but with limited u-v plane coverage, Balick and Brown⁶ proposed a model in which the non-thermal radio source consists of two components separated by 2.4 arcs and oriented almost north-south. Although this model has some similarity with the CCD data, further observations by Balick and Brown led them to reject it in favour of a single-component model. A more recent VLA map⁷ makes it clear that the powerful non-thermal radio source at the galactic centre does not have a double structure on the scale of arcseconds. This map (at 5 GHz) is, however, limited to a resolution of 2×8 arcs, which is insufficient to allow proper identification of the CCD images. Unfortunately, the different astrometric reference frames used at radio and optical wavelengths do not allow registration of the two maps to better than ~1 arcs. Thus one cannot rule out completely the possibility that the non-thermal radio source lies between the two newly-discovered objects, although this seems unlikely. The IR map can, of course, be precisely placed with respect to the CCD image by means of the visible field stars.

If the powerful 2.2-\(\mu\)m source IRS-7 is a late M supergiant, as is normally assumed, its apparent magnitude at 0.9 µm would be around 20. This is not much fainter than the sources detected by the CCD, and suggests that a deeper exposure would also detect this source.

If the flux from each of the newly discovered objects is due to stellar continuum at 10 kpc, then each source has a dereddened absolute magnitude in I of about -7.7. Because each image is unresolved it would be reasonable to ascribe all of this flux to a pair of individual stars. Each star would then need to be a supergiant, of spectral type K or earlier. This interpretation would be consistent with the objects being unimpressive at 2.2 µm, and with the lack of pronounced CO absorption⁸

The present results represent the shortest IR wavelength at which the galactic centre has been observed. It is therefore tempting to try to identify these objects with the ionization source for the region. Although the total flux required to power the 10 µm H II regions could be provided by a single O5 star, Lacy et al.9 have shown that this flux must be unusually soft, that is $T_{\text{eff}} \approx 35,000 \text{ K}$ (see also ref. 10), corresponding to something closer to an O9 star. It thus seems unlikely that a single pair of stars could be responsible for all the ionization. One cannot, however, rule out the possibility that the stars seen by the CCD are members of a larger cluster, whose overall ionizing output powers the region.

An alternative interpretation would be that the CCD images are due to line emission from two compact H II regions. The most plausible lines are the [S III] $^{1}D \rightarrow ^{3}P$, $J = 2 \rightarrow 1$ and $J = 2 \rightarrow 1$ 2 transitions at 9,069 and 9,532 Å respectively, with some additional contribution from the Paschen series of hydrogen. The He I 10,830 Å line would probably be too far down on the CCD response to be detectable. Assuming that all of the Brackett γ flux seen by Bally et al. 11 in an 8 arc s beam is due to the two compact sources, it is straightforward to calculate the expected [S III] flux under the assumption that the ionization state is similar to that of typical galactic H II regions. The resulting figure of 2×10^{-16} W cm⁻² is consistent with the observed, de-reddened value. Because of the very high spatial resolution of the CCD frame, it is not surprising that the two newly discovered objects are not prominent on previous, lowerresolution maps of the radio and Ne II emission.

The similarity of the two CCD images suggests that if the objects are compact H II regions, they may be ionized by a common source midway between them. Lacy et al. 12 have discussed in detail the possible existence of a $10^6 M_{\odot}$ black hole at the galactic centre. The ionizing flux from such an object would be more than sufficient to power the two compact sources found. We note that the separation of the sources $(4 \times 10^{17} \text{ cm})$ is 5,000 times greater than the expected diameter of the optically thick accretion disk of such a black hole.

The present data do not allow a unique identification of the sources detected by the CCD. It is of prime importance to obtain complete high spatial resolution maps of the region both in the 2.2 μm continuum and in Brackett γ , and to attempt to obtain spectra of the sources at 9,000 Å. This work will be attempted at the AAT as soon as possible. Meanwhile, radio maps at even higher resolution than the present VLA data would be desirable, as would improved registration of the optical and radio frames of reference. If the galactic centre sources turn out to be emitting strongly in [S III], then observations of the [S IV] line at 10.5 µm would yield a precise determination of the temperature of the ionizing radiation field. This would, in turn, place tight constraints on the nature of the ionizing source.

We thank the director of the AAO for allocating us time during the commissioning of the CCD to make these observations, D. Carter for help with the data taking and reduction, R. G. Dean for rescuing the data tape, D. A. Allen and P. Murdin for helpful discussions, and A. E. T. Schinckel for careful-measurement of the Palomar plate.

A simple ice sheet model yields realistic 100 kyr glacial cycles

David Pollard

Climatic Research Institute, Oregon State University, Corvallis, Oregon 97331, USA

Records of global ice volume for the past 700 kyr, based on oxygen isotopic data from deep-sea cores and reflecting mainly the changing Northern Hemispheric ice sheets, show a dominant cycle of roughly 100 kyr period. The records also show smalleramplitude oscillations with spectral peaks at roughly 40 and 20 kyr periods, which are well correlated with the Milankovich insolation variations due to perturbations in the Earth's orbital parameters. However, no model has accurately simulated the 100 kyr glacial cycle. Recently Birchfield et al. and Oerlemans have obtained encouraging agreement with some features of the glacial cycle by using a simple ice sheet model with a realistic time lag in the response of the bedrock to the ice load. This study extends their basic model, first by including topography to represent high ground in the north. Improved results can then be obtained but only with unrealistic parameter values and for some aspects of the record. Further improvements are

obtained by crudely parameterizing possible calving at the equatorward ice sheet tip during deglaciation by proglacial lakes and/or marine incursions from the Atlantic, as emphasized by Andrews³. The resulting ice volume curves agree fairly well with the observed records and their power spectra over the past 700 kyr.

The ice sheet model^{1,2} predicts ice thickness in a cross-section running approximately north-south along a typical flow line (see Fig. 4). A vertically integrated approximate ice flow law is used with east-west flow neglected, which reduces the ice dynamics to a non-linear diffusion equation for ice thickness h

$$\frac{\partial h}{\partial t} = A \frac{\partial}{\partial x} \left[h^{\alpha} \left| \frac{\partial (\dot{h} + h')}{\partial x} \right|^{\beta} \frac{\partial (h + h')}{\partial x} \right] + G(h + h', x, \text{ orbit})$$
(1)

where t is time and x is distance to the south. h' is the elevation of the bedrock surface above a fixed reference level (taken as the present mean sea level). For all results below $A = 5.77 \times 10^{-4} \,\mathrm{m}^{-3} \,\mathrm{yr}^{-1}$, $\alpha = 5$ and $\beta = 2$. The northern boundary of the model is taken at 74° N to represent the Arctic Ocean shoreline, where h is required to be zero (this excludes the possibility of marine ice sheets forming in the Arctic⁴). G is the net annual mass balance on the ice surface and crudely represents the current distributions of snowfall and ice melt. Its dependence on the surface elevation h + h' follows Oerlemans²:

$$G = \begin{cases} a(h+h'-E) - b(h+h'-E)^2 & \text{if } h+h'-E \le 1,500 \text{ m} \\ 0.56 & \text{if } h+h'-E > 1,500 \text{ m} \end{cases} \text{ m yr}^{-1}$$

where $a = 0.81 \times 10^{-3} \text{ yr}^{-1}$, $b = 0.30 \times 10^{-6} \text{ m}^{-1} \text{ yr}^{-1}$. At elevations below the equilibrium-line altitude E, G becomes rapidly negative (due mainly to summer air temperatures being above freezing), whereas above E, G increases more slowly to a maximum value. As in previous studies, E is assumed to have a constant slope in latitude and to be shifted uniformly by the insolation variations according to $E = E_0(x) + k\Delta Q$, where E_0 is the present equilibrium line and ΔQ is the difference in the summer half-year insolation at 55 °N from that of the present, calculated from the orbital parameters⁵. E_0 and the insolation sensitivity, k, are specified for each run below.

Fig. 1 Total cross-sectional area of ice versus time for various model versions (solid curves). The corresponding approximate ice volume can be obtained by multiplying by a typical east-west ice sheet dimension 3,000 km). The dotted curve in each panel is an oxygen isotope deep-sea core record minus its present value, redrawn from ref. 20. a, Model run with no topography $(h'_0(x) =$ 0) and with the bedrock in isostatic equilibrium $(\nu = \infty, h' = -rh)$; the present equilibrium line $E_0(x)$ passes through the (lat. (°N), height (m)) point (73, 0) with a slope of 0.9× 10^{-3} ; the insolation sensitivity $k = 25 \text{ m ly}^{-1}$ day; the ice/rock density ratio $r = 10^{-3}$ 0.3. b, As a except with bedrock lag $\nu = 100 \text{ km}^2 \text{ yr}^{-1}$ (in this and subsequent model runs, the maximum ice areas attained correspond to southern tip positions of ~49-52 °N). c, Model run with piecewise-linear topography $h'_0(x)$ joining the following (lat., height) points: (72, 0), (70, 850), (66, 200), (40, 400), (30, 400); the northern model boundary is at 72 °N; $E_0(x)$ passes through (66, 850) with a slope of 1.0×10^{-3} ; $k = 20 \text{ m ly}^{-1}$ day; $\nu = 100 \text{ km}^2 \text{ yr}^{-1}$; r = 0.4. d, Model run including the calving mechanism (equation (4)); $h'_0(x)$ joins (74, -500), (70, 850), (66, 200), (40, 400), (30, 400) (the calving mechanism operates permanently at the northern tip,

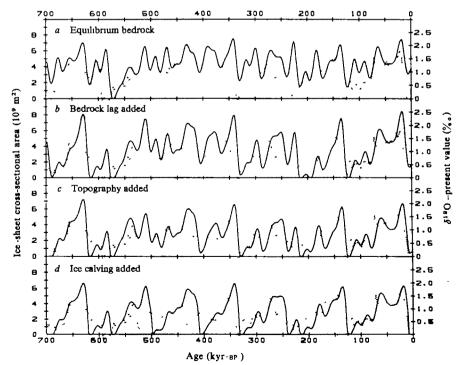

The response of the bedrock to the changing ice load consists of an elastic deformation of the lithosphere and a deeper viscous flow in the asthenosphere. As in other models^{1,2} the smaller elastic deformation is neglected here. It is not generally agreed whether the best asthenospheric model is closer to a relatively thin channel or a deep half-space⁶⁻⁸; the thin-channel model is used here, which with linear viscosity yields^{6,9}

$$\frac{\partial h'}{\partial t} = \nu \frac{\partial^2}{\partial x^2} [h' - h'_0(x) + rh] \tag{3}$$

where r is the ratio of ice density ρ_1 to rock density ρ_* ; ν is $\rho_*gH^3/N\eta$ where g is the gravitational acceleration, H is the mean thickness of the channel, η its dynamic viscosity, and N is 12 or 3 (depending on whether zero tangential velocity or zero tangential stress is required at the base of the lithosphere). $h'_0(x)$ is the surface topography due to crustal structure that would prevail in isostatic equilibrium without any ice. The choice of lateral boundary conditions for equation (3) is uncertain; for the runs below it was required that $h' = h'_0$ at the model boundaries 74°N and 30°N, but other reasonable choices have little effect on the results. The main effect of using equation (3) instead of a local-response equation^{1,2} is that the bedrock adjusts rapidly to small-scale ice loading, whereas the broad deep depressions under the largest ice sheets can be preserved for a much longer time during subsequent deglaciations.

Equations (1) and (3) were numerically integrated forward in time using a Newton-Raphson scheme for each equation individually, with an implicit contribution from every term involving h in the ice flow expression in equation (1). This allowed a time step of 50-100 yr with a latitudinal spacing of 55.5 km (= 0.5° lat.). Tests were made to check that the results agree adequately with those at higher resolutions. Many runs were made varying the parameters E_0 , k, r, ν and $h'_0(x)$, and the results are summarized in Fig. 1. For comparison a deep-sea core record is shown in each panel (dotted curve); this is interpreted here as being proportional to Northern Hemispheric ice volume, although it may also have been affected significantly by Antarctic ice sheet variations 10.

Figure 1a shows a run with no topography $(h'_0(x) = 0)$ and with the bedrock always in isostatic equilibrium with the ice load $(\nu = \infty$, that is h' = -rh). This is similar to results of earlier

maintaining it at ~72.5° N); $E_0(x)$ passes through (70, 550) with a slope of 1.0×10^{-3} ; $k = 17 \text{ m ly}^{-1}$ day; $\nu = 100 \text{ km}^2 \text{ yr}^{-1}$; r = 0.3; sea level S = 0 in equation (4).

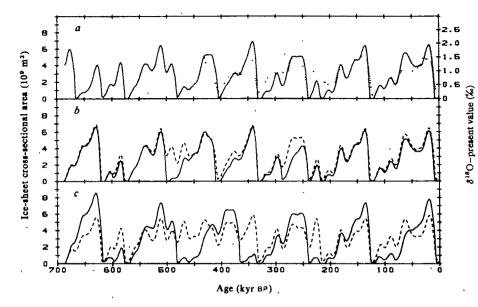

Fig. 2 a, Solid curve, as Fig. 1d except sea level $S = -100 \times$ (ice cross-sectional area/ 6×10^9 m²) m, and with different initial conditions. Dotted curve, oxygenisotopic deep-sea core record minus its present value, from the cores RC11-120 and E49-18, redrawn from ref. 29. b, Solid curve, as Fig. 1d except sea level S = 100 m. Dashed curve, as Fig. 1d except sea level S = -100 m. c, Solid curve, as Fig. 1d except $\nu = 30 \text{ km}^2 \text{ yr}^{-1}$. Dashed curve, as Fig. 1d except $\nu = 300 \text{ km}^2 \text{ yr}^{-1}$.

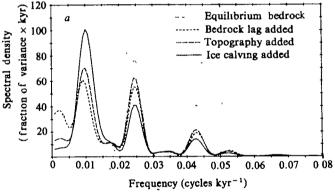

plastic ice sheet models^{11,12}, adequately reproducing the observed 20 and 40 kyr oscillations but with no trace of a 100 kyr cycle. The main features that this model lacks are the rapid retreats from glacial to interglacial conditions, for instance the last deglaciation from \sim 18 to \sim 6 kyr BP. These retreats are responsible for the asymmetric 'sawtooth' shape of the 100 kyr cycle and may even be essential to its existence. If the magnitude of the orbital forcing is increased in this model, the amplitude of the oscillations simply increases and also the ice sheet can vanish for extended periods, as in the earlier plastic models, however, no real resemblance to the observed glacial cycle can be obtained.

Figure 1b is produced with no topography but with $\nu = 100 \,\mathrm{km^2\,yr^{-1}}$, corresponding to a bedrock lag time of $\sim 10 \,\mathrm{kyr}$ for the broadest features. This curve is similar to that in ref. 1, with the bedrock lag producing some rapid deglaciations or partial retreats by the following mechanism: at a glacial maximum the bedrock depression is relatively deep, so that any subsequent retreat is amplified by the increased ice melt at the lower surface elevations near the southern tip. These retreats are initiated at times of high summer insolation and coincide well with some of the observed deglaciations; however, there is still only partial agreement with the observed records. One drawback is that to achieve the retreats, the amplitude of the orbital forcing, k, has to be set unrealistically large which results in too much power at high frequencies (see Fig. 3a).

Another disconcerting feature of Fig. 1b is that some of the retreats do not appear to be complete enough; for instance, the present day model ice sheet extends from the Arctic shoreline to 65.5° N, and during the period 550-350 kyr BP the southern tip never retreats beyond 65° N. However, it is not known exactly how far the real ice sheets retreated in earlier interglacials; the minimum δ^{18} O values for these times in various deep-sea cores are sometimes less and sometimes greater than today's value. Ice volumes can also be inferred from eustatic changes in sea level measured by raised coral reefs, and during the last interglacial at ~125 kyr BP the sea level was ~5 m higher than at present13, suggesting that the Northern Hemisphere was at least as ice-free as today. Unfortunately, sea-level estimates for the earlier interglacials are more uncertain due to tectonic uplift, and show only that the ice volume must have been a small fraction of that during an ice age¹³.

At this point the model seemed to need more potential for complete deglaciations, but with less amplitude of the orbital forcing. This was attempted first by including topography in the model. The high ground on the Labrador-Ungava Plateau and/or Baffin Island has often been considered as important for the inception of ice sheets, and has been included in several

recent models ¹⁴⁻¹⁶. Figure 1c shows a run with the topographical term h'_0 in equation (3) roughly representing a present day section running south-southwest from Baffin Bay, over the high ground on Baffin Island, through Hudson Bay and on into the central USA; added to this is the residual depression from the last glaciation of up to 300 m centred on Hudson Bay¹⁷. The most important feature is the Baffin Island plateau with a peak at 70° N, and similar results can be obtained with this feature alone. By carefully adjusting the mean equilibrium line E so that it occasionally intersects the peak, small ice sheets can

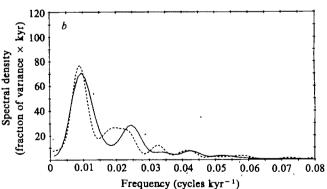

Fig. 3 a, Power spectral density for the model runs shown in Fig. 1. These were generated from time sequences of 350 points taken from each run at 2 kyr intervals, and detrended with a linear least-squares fit before computing autocovariances. A Tukey window was used with the number of lags $=\frac{1}{3}$ of the total number of points. b, Power spectral density for the two deep-sea core records shown as the dotted curves in Figs 1 and 2a. These were computed as for the model curves above. Dashed curve from ref. 20; solid curve from ref. 29.

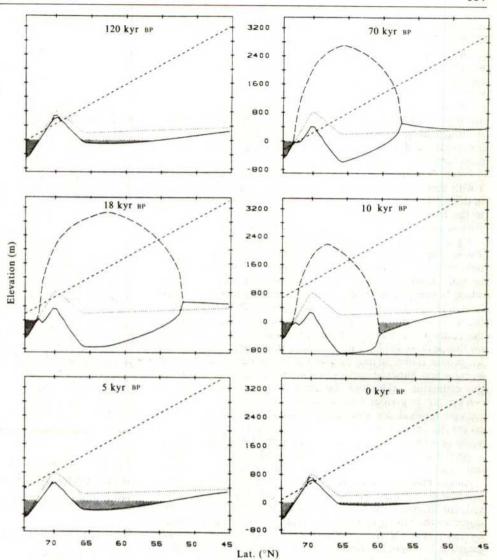

Fig. 4 Cross-sections versus latitude and height showing the ice sheet surface (long-dashed line) and the bedrock surface (solid line) at various times in the model run of Fig. 1d. Also shown are the equilibrium line E (short-dashed line) and the undisturbed topography h_0' (dotted line). The shaded regions show the extent of the invading water body that attacks the ice according to equation (4).

easily be initiated and grow out from the peak, whereas to the south E can still be high enough to place large ice sheets in jeopardy of complete deglaciations. Although the curve shows some improvement between ~ 350 and 0 kyr BP, the greater deglaciations were achieved only after careful tuning, especially in matching E to the topography. In addition an unrealistically large value for the ice/rock density ratio, r=0.4, was required, and the required amplitude of the orbital forcing, k, still results in too much high-frequency power (see Fig. 3a). Even so, the period from 550 to 350 kyr BP still contains no complete deglaciations. Also the growths out of the interglacials at ~ 330 and 215 kyr BP are unrealistic, with anomalous partial retreats occurring at 285 and 170 kyr BP respectively.

These shortcomings indicated that an additional mechanism was required to yield a more robust model. It was noted that during the retreats in Fig. 1c coinciding with the observed deglaciations the southern tip of the ice sheet temporarily dropped far below sea level. Andrews3 has emphasized that rapid calving by vast proglacial lakes, which are known to have existed around the southern Laurentide ice sheet perimeter during the last deglaciation, may be the only plausible mechanism capable of producing the observed rapid rates of retreat. This view is supported by deep-sea core evidence of Ruddiman and McIntyre 18, who infer massive discharge of icebergs into the North Atlantic after ~16 kyr BP. In addition marine incursions up the St Lawrence river and later into Hudson Bay at -8 kyr BP are known to have greatly accelerated the retreat3. The calving process was included in the model by setting the mass balance G equal to a large negative value at ice sheet points between the tip and the first interior ice sheet grid point

able to block the invading body of water. The invading water, whose surface is taken to be at sea level, can penetrate into the ice sheet only as far as the ice columns can be floated by its hydrostatic head, so that

$$G(x_{i+1}) = -20 \text{ m yr}^{-1} \text{if} \qquad \boxed{\rho_1 h(x_i) < \rho_w(S - h'(x_i)) \\ \text{and } h'(x_{i+1}) < S}$$
(4)

where ρ_w is the density of sea water, S the elevation of the current sea level and i the spatial grid index increasing into the ice sheet. Condition (4) is generally only satisfied, if at all, at the outermost $\sim 50-150$ km of the ice sheet when the tip is below the level S. The arbitrary value of -20 m yr⁻¹ in equation (4) is comparable with estimates by Andrews³, but is much less than those suggested by analogies with non-floating calving glaciers today¹⁹.

Figure 1d shows a run including this calving mechanism and with the topography described above. Deglaciations, now augmented by equation (4), can occur with a reduced amplitude of the orbital forcing, and the overall agreement with the observed record is improved considerably. Interestingly the high insolation anomaly that triggers the deglaciation at 410 kyr BP is considerably weaker than those at some other times, for example around 175 and 85 kyr BP. Deglaciations do not occur at the latter times because the ice sheet is too small and the bedrock surface too high to allow calving.

There are still some disagreements with the observed records, especially before ~400 kyr BP; however, before this time the observed records themselves tend to diverge from each other 1,20. In fact, the apparent agreement can be improved by

selecting another deep-sea core record for comparison, as shown in Fig. 2a. For this model run the sea level S was made a linear function of ice volume and different initial conditions were chosen to show the relative insensitivity of the model with calving (in fact, much the same results can even be obtained with less realistic flat topography southward of 72° N). The effects of varying most of the model parameters have been investigated, and two examples are shown in Fig. 2b and c. Although these parameter changes are fairly substantial, the occurrence and phase of most of the main glacial cycles are preserved.

Figure 3 compares the spectra for the model curves in Fig. 1 with those of the deep-sea core records. A gradual increase in the ~100 kyr peak is seen as each new mechanism is added to the model. The spectrum with the calving mechanism has relative peak sizes in good agreement with those observed.

Figure 4 illustrates the last glacial cycle of the run in Fig. 1d. The ice sheet appears first on the northern peak at 120 kyr BP, then grows out to its maximum size which makes it susceptible to rapid deglaciation triggered by a period of high insolation, which begins just after 18 kyr BP. The calving mechanism sets in at ~ 11 kyr BP when the ice sheet tip is at 57° N, and enables the ice to vanish completely just after 5 kyr BP. By the present the bedrock has rebounded enough to support a small ice cap on the peak at 70° N. This is smaller than the present Barnes ice cap on Baffin Island, despite the model equilibrium line E being a few hundred metres below that suggested by present day estimates²¹. Although the amount of bedrock uplift since ~8 kyr BP is greater than observed by factors of ≤ 2 , the present residual depression agrees roughly with that implied by gravity anomalies¹⁷, and the present region below sea level south of ~66° N corresponds roughly with that of Hudson Bay.

As the simple model used here is tested mainly against just one type of observed record, any positive results should be regarded mainly as a guide for future work. Many feedback processes involving other parts of the climate system are neglected; for instance, the improvement in the model curves produced by the calving mechanism might also have been produced by any highly ablative mechanism that can be triggered only after the ice sheet has reached maximum size. One example is the freshening and shallowing of the oceanic mixed layer by massive ice sheet runoff, a self-amplifying mechanism thought primarily to reduce snowfall in winter 22 and recently supported by deep-sea core evidence²³.

Equation (4) is an extremely simplified parameterization of the complex and not well understood mechanism of calving. An improved treatment would probably require the inclusion of east-west topography and ice sheet structure; with the present model equation (4) cannot distinguish between the known marine incursions from the east (up the St Lawrence river channel and into Hudson Bay, around each side of the Labrador-Ungava plateau), and the inland proglacial lakes that formed around the retreating Laurentide perimeter. Marine deposits from the past several thousand years are found only in the vicinity of the St Lawrence and the shores of Hudson Bay^{3,17}. This implies that the inland proglacial lakes formed mostly above sea level, in apparent disagreement with the model whose equatorward tip consistently drops a few hundred metres below sea level during deglaciation (Fig. 4). However, the basic mechanism represented by equation (4) is known to have induced rapid ice sheet disintegration when the sea invaded Hudson Bay at ~8 kyr BP (refs 3, 24), and is suspected of having induced past disintegrations of the West Antarctic ice sheet²⁵. The scenario hypothesized here could also apply to the Fennoscandian ice sheet, where the Scandinavian mountains form a northern plateau for ice sheet inception and the low-lying Baltic regions could have allowed the calving mechanism to be active during deglaciation.

Possible further work includes an extension of the model to three dimensions^{15,26}, improved treatment and comparison with data of calving by water bodies after ~16 kyr BP (refs 3, 18), inclusion of the elastic response of the lithosphere²⁷, and a test of the results using a deep half-space asthenospheric model²⁸. In addition equation (2) can be replaced by coupling to a global seasonal climate model^{12,16}.

Interaction of cryospheric forcings with rotational dynamics has consequences for ice ages

Recent geological evidence^{1,2} suggests that several degrees of true polar wandering have occurred since the mid-Pliocene. This rotational instability is supported by dynamical calculations3 of the spin axis of a layered viscoelastic Earth, which has been subjected to the periodic forcings characteristic of the late Cenozoic ice age. We propose here that polar wandering, induced by the intrinsic response of the viscoelastic planet to such cryospheric forcings, may be the underlying cause for the termination of the present ice age epoch.

In the past decade there has been an increasing number of observations4-7 based on the correlation between the periodicities of the Earth's orbit and the time series analyses of the oxygen isotope data to suggest that there is a cause and effect relationship between the two systems. Nonetheless, it has been argued that internal stochastic mechanisms⁸⁻¹⁰ could be an important source for climatic variations. A new generation 11-14 of climatic models has also emphasized the need to include the non-linear response of an ice sheet to changes in solar radiation in the attempt to understand better the mechanisms of ice ages. Here we pursue this theme and focus attention on the long-term effects of cryospheric forcings on producing secular motions of the Earth's spin axis, more commonly known as true polar wandering (TPW). The important consequences of TPW on the evolution of the climate system over a long time scale had long been appreciated 15 and Gold 16 had proposed that polar wandering is not only physically feasible but is to be expected for a viscoelastic planet.

3

First, we consider the recent findings 1-3 that suggest that there may be a connection between the late Cenozoic glaciation and TPW of ~5° in the past 10 Myr, as revealed by the recent reanalyses of the paths of palaeomagnetic poles. These data are based on the reconfirmation that hotspots remain relatively fixed with respect to one another for the past 150 Myr. Calculations based on a layered viscoelastic Earth have supported this hypothesis that such an amount of polar wander relative to the entire mantle could, in fact, have occurred in response to the waxing and waning of large ice sheets in the past few million years. Over a shorter time scale, evidence¹⁷ from the past 75 years of International Latitude Service data also shows that TPW is taking place today. This phenomenon can be shown to be the direct consequence of the late Wisconsin deglaciation on the Earth's rotation 18,19. Thus evidence is accumulating to the effect that cryospheric forcings can strongly influence polar motions for a wide range of time scales. Our model calls on polar wander induced by ice ages ultimately to exceed a critical value of angular displacement which will dislodge the present climatic trend from its apparent equilibrium configuration. Such a finite-amplitude perturbation in the amplitude of rotation may cause the termination of ice ages. This event cannot be explained by Milankovitch's theory of astronomical forcings.

We now present our model which provides a physical descrip-

tion of polar wander produced by glaciation.

The expression of the conservation of the system angular momentum associated with the cryosphere and solid Earth is given by the Eulerian equations of motion, more commonly known in geophysics as the Liouville equation²⁰. For forcing functions from glacial loadings it takes the vector form

$$\frac{\mathrm{d}}{\mathrm{d}t}(\mathbf{J}\cdot\boldsymbol{\omega}) + \boldsymbol{\omega}\times\mathbf{J}\cdot\boldsymbol{\omega} = 0 \tag{1}$$

which is applicable for a body-fixed coordinate system rigidly attached to the Earth as a whole with its origin at the centre of mass and with the axes oriented such that the inertia tensor J initially is diagonal. ω is the angular velocity vector.

The J tensor as a function of time t may be decomposed as follows.

$$\mathbf{J}(t) = I\delta_{\mathbf{u}} + C_{\mathbf{u}}(t) + I_{\mathbf{u}}(t) \tag{2}$$

where I is the diagonal inertia tensor of a bulging Earth in the absence of rotational fluctuations, $C_q(t)$ is the component of the inertia tensor due to changes in the basic rotation rate, and $I_q(t)$ is the contribution produced by transient viscous flow in the mantle and by shape deformation due to the glacial forcings. Variations in $I_q(t)$ drive the spin axis away from its original position, whereas $C_q(t)$ acts as a stabilizing agent in the readjustment of the rotational bulge as a consequence of the sudden change in the moment of inertia.

The nonlinear version of the Liouville equation must be used for polar displacements >20° (ref. 19). But for the amount of polar drift found in the past 10 Myr (refs 1, 2) the linearized Liouville equations may be employed with sufficient accuracy. The solution has the simple Laplace transform domain form

$$\mathbf{m}(s) = \frac{\psi(s) + \phi(s)}{\left(1 + \frac{i}{\sigma_r} s\right)}$$
(3)

where $\mathbf{m} = (m_1, im_2)^T$ are the directions cosines of the rotation axis in the body-fixed coordinate system, s is a complex number and σ_r is the Chandler wobble frequency for the rigid Earth. $\psi(s)$ and $\phi(s) = (\phi_1, i\phi_1)^T$ respectively are the forcing functions arising from rotational deformation and the surface loading from ice masses. They have the explicit forms

$$\psi(s) = \frac{k_2^T(s, a)\mathbf{m}(s)}{k_t} \tag{4}$$

$$\phi_1(s) = \frac{I_{13}(s)}{C - A} + \frac{(sI_{23}(s) - \bar{I}_{23})}{\Omega(C - A)}$$
 (5)

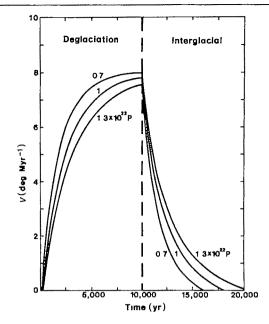

Fig. 1 Instantaneous speed of polar wandering during a glacial cycle. The length of time of the deglaciation phase is taken to be 10⁴ yr, characteristic of the late Wisconsin. The speed of polar wander is taken to be positive when the direction of motion is towards the glaciating area. The end of the last deglaciation phase is around 5-6 kyr BP.

$$\phi_2(s) = \frac{I_{23}(s)}{C - A} - \frac{(sI_{13}(s) - \overline{I}_{13})}{\Omega(C - A)}$$
 (6)

where Ω is the diurnal rotation rate, C and A are the axial and equatorial moments of inertia respectively and the overbars denote quantities at time t=0. $k_2^T(s,a)$ is the tidal Love number, which represents the time-dependent behaviour of the gravitational potential in response to fluctuations in the rate of rotation, for angular order l=2 evaluated at the surface (r=a) and k_l is the fluid Love number, which is a measure of the Earth's yield to centrifugal deformation over a time scale $0 (10^9 \text{ yr})$. Its value is about 0.95 (ref. 20).

For a given Earth model, $k_2(s, a)$, $I_{13}(s)$ and $I_{23}(s)$ can be obtained spectrally from the solution of a boundary value problem. Using a three-layer model, which consists of an elastic lithosphere, a viscoelastic mantle, and an inviscid core, we have obtained analytical expressions³ for the spectral decomposition of equations (4)–(6), which greatly facilitates the solution of the initial value problem of the polar displacement as a result of glacial forcing.

This three-layer model contains the essential physical ingredients needed for polar wander to occur. (1) The lithosphere is not isostatically compensated in the final state. Thus this residual elastic strain field produces a net polar displacement after the completion of a glaciation cycle. (2) Transient viscous flow in the mantle is influenced by the core and thereby produces another relaxation mode, whose strength of excitation is of the same order as that associated with the mantle mode.

The best available data which provide information on the actual time dependence of the extent of Pleistocene glaciation are the time series of oxygen isotope variability^{5,21}. To show that rapid rates of polar wander can occur at the glacial-interglacial boundary, we have conducted a series of model calculations for contributions from the two major ice sheets in the Northern Hemisphere, Laurentide in North America and Fennoscandia in Europe. A total mass of 2.4×10^{19} kg has been used in the loading and unloading process. For mathematical convenience a ramp-shaped function with an accretion time of 9×10^4 yr and with a disintegration time of 10^4 yr has been used to describe the climatic fluctuations³. This time-dependence can be transformed readily in the Laplace transform domain and used in equation (3). Figure 1 shows that with a range of

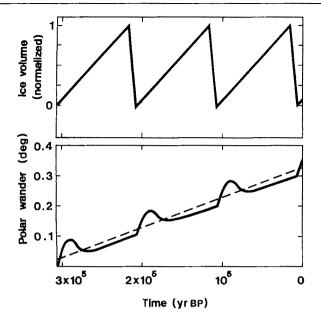

Fig. 2 Polar wander caused by cryospheric forcings. The forcing function is given at the top by the time-dependence of the ice volume, which has been normalized by an ice volume which is equivalent to a 70-m rise of the global sea level, a representative value of the unstable ice sheets in the Northern Hemisphere³³. The time of termination of the last deglaciation phase is taken to be 6 kyr BP. The response of the rotating viscoelastic Earth to such forcings takes the form of polar wandering. During this period the dashed line stands for the long-term polar displacement, whereas the solid line represents the short-term polar movements in response to glaciation and deglaciation.

mean mantle viscosities $0 (10^{22}P)$ quite rapid rates of polar wander, up to 8° Myr⁻¹, which translates into around 80 cm yr⁻¹, can take place. However, as the period of deglaciation, $0 (10^4 \text{ yr})$, is short, the total polar displacement is only about 10 km. This amount, which involves polar motion relative to the mantle, is much smaller than changes in the obliquity, which involves polar motion relative to the fixed stars. This latter phenomenon arises from an external torque and may amount to 3-4°. Therefore, we would not expect our sporadic rapid motions of 80 cm yr⁻¹ to have much of a visible signature on the ice coverage record. However, these rapid secular changes of the rotation axis may have some unforseen effects on climatic variations²² between 10^3 and 10^4 yr.

Given that such rapid polar wander can occur in response to a single glaciation cycle, what then are the long range prospects for the late Cenozoic ice ages, which from the proxy climatic record seem to have reached a quasi steady-state trend consisting of a saw-tooth pattern for the past million years 5.23,24? To assess this possibility we have calculated the amount of polar wander, which has occurred since the mid-Pliocene from a forcing function which has been constructed on the basis of the proxy climatic record 5.23. Our calculations indicate that an average polar wander speed of 1° Myr⁻¹ is attained for a viscosity of 10²²P.

These modelling results suggest that cryospheric forcings must be capable of producing TPW because of the basic physics due to the Earth's viscoelastic rheology¹⁶. If the present pattern of ice age cycles remains unchanged, then, barring any sudden changes of present plate motions, which might counteract the effects of TPW, Antarctica would begin to drift northward gradually by virtue of TPW. At the initial stages of this secular drift climatic warming may cause an increase of the melting from the Antarctic ice shelves. Over a short time scale, 0 (10²-10³ yr), continued weakening of the ice shelves²⁵ would then result in the ultimate collapse of the weakened portion of the Antarctic ice sheet with a consequent worldwide rise in the sea level of at least a few metres.

In the prevailing conditions of the Cenozoic ice ages, the entire mantle would shift relative to the spin axis. In this connection, data which have been combined from equatorial sediment facies²⁶ and palaeomagnetism²⁶, strongly support the occurence of TPW, at least since the Cretaceous. They yield a motion of the rotation axis with a direction of about 25°E (towards Eastern Europe) in a reference frame in which the hotspots are fixed^{1,26}.

Secular motion of the Earth's spin axis relative to the geographical distribution of oceans and continents can have a profound influence on the future trend of the current ice age cycles. Milankovitch²⁷ considered that variations in the orbital configuration are critical for rapid growth of ice sheets in the Northern Hemisphere. The magnitude of the orbital variations are of a few degrees^{28,29}. Hence, if the present trend of polar wander were to exceed a certain threshold value, 0 (10°), then such a large perturbation may bring about drastic changes in the climate system, such as changes in the role of the Coriolis forces, which control the patterns of oceanic currents to a large extent. Situated adjacent to the largest Northern Hemisphere ice sheets of the ice ages, the mid-latitude North Atlantic Ocean has, indeed, an important role in the Earth's recent climate history³⁰. One would expect, therefore, that under these circumstances of a shift in the direction of the Gulf Stream the response of the climate system to orbital variations might be altered drastically.

To demonstrate the feasibility of this mechanism, we have calculated in Fig. 2 the amount of TPW due to the periodic forcings from ice ages in the past 3×10^5 yr. For a mean mantle viscosity of 10²²P, the speed of polar wander is about 1° Myr⁻¹. The saw-tooth curve of the Quaternary Ice Age shows clearly a 10⁵-yr quasi-periodicity^{21,23}. The occurrence of an increasing trend in polar wandering in response to continual cryospheric forcings is a natural consequence of the rheological behaviour of the Earth. The time scale for this quasi-steady period is 0 (10 Myr), if the average polar wander speed is maintained steadily at 0 (1° Myr⁻¹) as shown in Fig. 2. Angular displacements of this magnitude would seem sufficient to displace the present configuration of continents and ocean circulations from the state of quasi-equilibrium which it now seems to enjoy. From then this new set of surface boundary conditions will not act in concert with astronomical forcings to produce large scale continental glaciation.

Finally, for each epoch of ice ages, the magnitude of the cryospheric forcings is governed by the particular geographical distribution of continental platforms, which may be linked with the possible time-dependent nature of mantle convection. For the Cenozoic ice age, whose inception is still fraught with uncertainties^{31,32}, we may expect this present periodic phase to persist for another few million years, before it undergoes self-destruction by TPW.

Picrites as parental magma of MORB-type tholeiites

D. J. Beets*, G. Th. Klaver*, F. F. Beunk*, C. Kieft† & P. Maaskant‡

* Geological Institute, University of Amsterdam, Nieuwe Prinsengracht 130, Amsterdam, The Netherlands † WACOM, and ‡ Department of Earth Sciences, Free University, Amsterdam. The Netherlands

Recent experimental work on peridotites and basalts 1-3 and a reappraisal of ophiolite complexes4 supports the concept that basalts are derived from picritic parents⁵⁻⁷. The occurrence of a density minimum in the liquid line of descent⁸⁻¹⁰ explains why mid-ocean ridge tholeiites fall in a restricted compositional range, and parental picrites can only be found in the exceptional case when eruption is not yet controlled by a steady-state magma chamber^{7,11}. We present here a preliminary account of a natural example of such a case from the Caribbean.

The Cretaceous Curação Lava Formation is a more than 5-km thick succession of submarine basalts with more than 20 flows of picritic pillow basalts in its lower part. The base of the succession is not exposed. The picrites are associated with variolitic basalts and olivine-phyric tholeiites. Olivine-phyric and plagioclase-pyroxene-phyric tholeiites make up the bulk of the formation, the latter predominating in the upper part. Composition of glass and of olivine megacrysts and phenocrysts in the picrites indicates that the olivine-phyric tholeiites were derived by fractionation of olivine from a picritic parent with at least 17.5 wt% MgO. The plagioclase-pyroxene-phyric tholeiites are derived by further fractionation of olivine, plagioclase and pyroxene. The picritic basalts in the section have 19-31 wt% MgO, which shows that part of their olivine is cumulative. Model calculations suggest that the parent results from 30% partial melting of a mantle of pyrolitic composition.

The variolitic basalts associated with the picrites in the lower part of the unit, pose a problem. Major element chemistry of these rocks show that they are not related to the other basalts by low pressure fractionation. However, incompatible element ratios are roughly similar for all basalts of the succession, which suggests that they are derived from the same mantle source.

The island of Curação (positioned between 12°2' N and 12°23'30" N, and 69°10' W and 68°44'30" W) is the larger of an east-west-trending group of small islands in the southern Caribbean. Geophysical and geological evidence suggests that the islands are underlain by a basement of oceanic crust of pre-Campanian age¹². The Curação Lava Formation is the lowermost unit exposed in Curação 13. It consists almost entirely of volcanic rocks but contains one intercalation of a few metres thickness of pelagic sediments in its upper part. These contain an ammonite fauna of middle Albian age¹⁴. The Curação Lava Formation consists largely of pillowed flows. They are virtually the only rock-type in the lower half of the formation; in the upper half they are still predominant, but alternate with reworked hyaloclastites and dolerite sills and dykes. A sheeted dyke complex is not exposed.

Whole-rock major elements used here have been determined by X-ray fluorescence spectrometry (University of Amsterdam); rare earth elements (REE) by instrumental neutron activation analysis (Inter-university Reactor Institute, Delft); glass and minerals were analysed with an electron microprobe (Instituut voor Ardwetenschappen, Vrije Universiteit, Amsterdam).

Most picrites contain between 19 and 22 wt% MgO (Fig. 1). These flows all have pillow structure and vary in thickness from a few tens of metres to roughly 100 m. Pillow shape and size is equal to those of the tholeiites. The rocks consist of more or less euhedral olivine phenocrysts (Fo_{86.5-87.4}) of up to 2.5 mm in size, embedded in a groundmass of glass and skeletal quench crystals of olivine and clinopyroxene. The amount of glass decreases rapidly from rim to core of the pillows. Chrome-rich spinel occurs as an accessory constituent. The olivine phenocrysts are unzoned. They make up 27-32 vol.% of the lavas. Gravitational settling of olivine within a flow or within a single pillow is negligible, and the proportion of olivine always falls within these limits. Glass from the pillow margin of one of these picrites (79KV615, Table 1) plots on the Fo₈₇ control line and within the field of the olivine-phyric tholeiites (Fig. 1). This glass (MgO = 10.6%, FeO = 8.6%) is similar in composition to the most primitive liquids erupted at mid-ocean ridges. It is in equilibrium with the Fo_{87} phenocrysts, using a K_D for partitioning Mg and Fe between olivine and melt of 0.3 (ref. 15). This implies that the olivine-phyric tholeiites are derived from a parent with a MgO-content ≥10.6 by equilibrium crystallization of olivine. The occurrence of strongly resorbed olivine mega-

crysts up to 5 mm long and with a composition up to Fo 91.4 (Table 2, Fig. 1) in three of the picritic flows brings us nearer to a conclusion about the composition of the parent. Assuming that they represent early formed, non-equilibrated phenocrysts, the composition of the melt in which they formed can be calculated using Roeder and Emslie's K_D of 0.3 and the MgO variation diagram (Fig. 1). This melt (Table 2) has about 17.5% MgO. A slightly higher K_D would give a parent within the range of the pillowed picrites (MgO 19-22%); the use of an oxidation ratio lower than the value assumed for the picrites (0.1) has the same effect: taking total Fe as FeO gives a parent with 19.9% MgO.

Accumulation of olivine is evident in the picrites with a MgO content of 25-31 wt%. These olivines are rounded and partly resorbed. In the most Mg-rich flows olivine forms up to 60 vol.%.

The control line of the MgO variation diagram (Fig. 1) changes in slope between 8 and 9 wt% MgO, indicating that fractionation of plagioclase and pyroxene defines the composition of the more evolved tholeiites. The variolitic basalts, with a MgO wt% similar to that of the olivine-phyric tholeiites, systematically plot outside the fractionation trend of most of the volcanics of the Curação Lava Formation.

The chondrite-normalized REE patterns (Fig. 2) of picrites, olivine-phyric tholeiites and plagioclase-pyroxene phyric tholeiites are consistent with consanguinity of the suite. They are basically flat (T-type MORB; La/Sm_N = 0.8-1.0). From the MgO/Sm ratio the REE content of the parent can be estimated to be about 6 times chondritic. Assuming that the mantle source is twice chondritic^{1,16}, the parent magma would represent about 30% batch partial melting. This amount of melting would leave a residue of olivine and orthopyroxene only. Although residual rocks of the Curaçaoan succession are not known, a model calculation is given in Table 2, using the olivine megacrysts (Fo_{91.4}) of sample 79Be148, and an orthopyroxene of Green et al.¹. A small amount (0.5%) of a chrome-rich spinel from sample 79KV615 is added to the residue, mainly to raise the Cr₂O₃-content of the source to acceptable values. The model calculations are furthermore constrained by: (1) composition of the residue, that must fall within the field of that of natural, mantle derived periodites¹⁷; (2) 3-4 wt% CaO and 4-5 wt% Al₂O₃ in the source composition, that is compositions similar to previous estimates of upper mantle pyrolite18. The first constraint, in combination with 30% partial melt, mainly defines the proportions of the residual phases as approximately 80% olivine and 20% orthopyroxene. A much higher amount of orthopyroxene would give a residue too high in SiO2 and too low in MgO. The second contraint necessitates the selection of an Al₂O₃-rich orthopyroxene. The residual orthopyroxene of

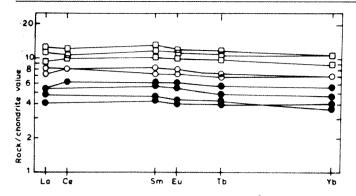

Fig. 2 Chondrite-normalized REE-patterns of representative basalts of the Curação Lava Formation. O, Picrites; O, olivinephyric tholeiites; \square , plagioclase-pyroxene-phyric tholeiites. MgO-content of the basalts are, from base to top: 27.5; 25.1; 21.0; 20.7; 11.0; 10.3; 8.3; 6.0; 4.9.

Green et al.¹ best fits our needs, and gives a source (Table 2), which is in good agreement with that of earlier calculations^{1,18}. The main difference with the source of DSDP 3-18 (ref. 1) is the much higher K₂O-content, reflecting the transitional nature of the Curaçaoan basalts.

The common occurrence of picritic flows in the lower part of the Curação Lava Formation suggests that, at this stage of development of the volcanic unit, magma reservoirs are small. They enlarge as the volcanic pile builds up, and the height of the magma column between reservoir and surface becomes such that the dense picritic liquid can no longer extrude. Fractionation of olivine, and, at a later stage, of pyroxene and plagioclase in these reservoirs, provide the less dense tholeiites of the upper half of the formation. These considerations suggest that the Curação Lava Formation was formed because of the initiation of a new system, rather than being a fragment of oceanic crust fed by a steady-state magma chamber. The new system is not the opening of the Caribbean, as this occurs much earlier¹⁹. Considering the close association of the unit in space and time with volcanic sequences of island-arc origin (late Albian to Coniacian on the neighbouring islands of Aruba and Bonaire²⁰), we consider the unit to be the base of an island-arc succession formed either during the initiation of subduction²¹, or because of lengthening of an existing arc at a trench-trench-ridge triple junction. These models will be discussed more fully elsewhere.

Fieldwork in Curação was made possible through grants WR 75-211, 212 and 213 of the Netherlands Foundation for the Advancement of Tropical Research (WOTRO). We thank M. de Bruin and co-workers, I. S. Oen, H. J. MacGillavry and J. Grocott for help, and ZWO-WACOM for financial and personal support.

Seabed-wave resonance and sand bar growth

A. D. Heathershaw

Institute of Oceanographic Sciences, Crossway, Taunton, Somerset TA1 2DW, UK

The interaction of surface water waves with undulating sea-bed topography is of fundamental importance to coastal engineers and sedimentologists. For example, wave reflection from submerged bars on beaches may provide a mechanism for protecting the beach from further wave attack. Additionally the interaction of surface water waves with other tidally or wave generated bedforms, such as sandwaves on offshore banks, may modify wave climates on adjacent coastlines. While there have been numerous studies of the interaction of sea waves with engineering structures, such as breakwaters, piers, and jetties, there have been comparatively few investigations of wave interactions with naturally occurring bedforms. Predictions have recently been made of the amount of wave energy reflected as a result of resonant interactions between surface water waves and undulating sea-bed topography but with no supporting experimental proof. I describe here preliminary results from what are believed to be the first published laboratory measurements of resonant interactions between surface water waves and submerged bars which show that significant and large amounts of wave energy may be reflected and that these reflections are brought about by resonant interactions between surface-water waves and the bedforms. In particular, at resonance, incident surface water wavelengths are approximately twice the bedform wavelengths. These results have implications not only in terms of wave reflection from naturally occurring bedforms, say bars on beaches, but also for sediment transport processes in general.

Davies^{1,2} has used linear perturbation theory to show that to

a first approximation, wave reflection from a finite number of submerged sinusoidal bars, having small amplitude and on an otherwise plane bed, is given by

$$K_{r} = \frac{a_{r}}{a_{i}}$$

$$= \frac{2bk}{\{2kh + \sinh(2kh)\}} \left(\frac{2k}{l}\right) \frac{\left|\sin\left(\frac{2k}{l}m\pi\right)\right|}{\left(\frac{2k}{l}\right)^{2} - 1}$$
(1)

where K_r is the wave reflection coefficient, a_r and a_i are the reflected and incident wave amplitudes respectively, well away from the region of bedforms, b is the bar amplitude, h is the water depth, m is the number of bars and k and l are the free surface and bar wavenumbers. Here $k = 2\pi/L$ and $l = 2\pi/L_b$, where L and L_b are surface and bar wavelengths respectively. In the theory it was assumed that the wave crests were parallel to the bars and that the flow was non-separating. Additionally, certain constraints were imposed on the result (equation (1)) which included the following: $a_i k$, $a_i h$, $a_i / k^2 h^3$, bl, b/hand $bk \ll 1$. Furthermore, unless the solution is corrected for wave attenuation across the bars (see later) it is required that $|a_r/a_i| \ll 1$.

Following Davies¹, the result in equation (1) may be considered in two parts the second of which we shall denote as

$$H\left(\frac{2k}{l}\right) = \left(\frac{2k}{l}\right) \frac{\left|\sin\left(\frac{2k}{l}m\pi\right)\right|}{\left(\frac{2k}{l}\right)^2 - 1} \tag{2}$$

Equation (2) illustrates that for a given number of bars (m),

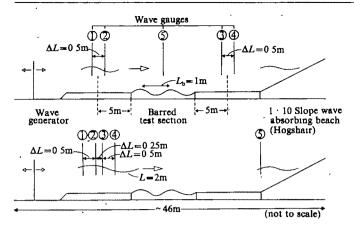

Fig. 1 Positions of gauges, in relation to barred test section and wave absorbing beach, for two main types of measurements. Typical values of the wave gauge spacing ΔL are also shown.

the wave reflection coefficient is oscillatory in 2k/l, that is the quotient of twice the surface wavenumber and the bed wavenumber. The reflection coefficient is also resonant in the region $2k/l \approx 1$ and, at 2k/l = 1 itself, $H(2k/l) = m\pi/2$ which suggests that peak reflection coefficients are linearly dependent on the number of bars present.

To test Davies'^{1.2} theoretical predictions and in particular equations (1) and (2), detailed measurements of wave reflection from submerged bars were carried out using the $45.72 \times 0.91 \times 0.91$ m wave tank facility at the Coastal Engineering Research Center, Virginia. A 10-m long test section consisting of 10×1 m wavelength, 0.05-m amplitude sinusoidal bars was constructed in the tank and set in a false bottom. The barred test section was situated approximately midway between a hydraulically driven piston type wave generator, at one end of the tank, and a 1:10 slope wave absorbing beach at the other. Water surface elevations were measured using standard parallel-wire resistance type wave gauges and wave reflection coefficients determined using the method of Goda and Suzuki³.

Two pairs of gauges and a single gauge were used to make two types of measurement of which some preliminary results are shown here; first incident and transmitted wave conditions were measured with one gauge pair 5 m on the up-wave side of the bars and the second gauge pair 5 m on the down-wave side. The remaining gauge was positioned midway along the test section. The up-wave gauge pair thus gave information on wave reflection from the bars while the second gauge pair provided data on the transmitted wave heights and the amount of wave energy reflected from the beach. In the second type of measurement two pairs of gauges were moved along the tank

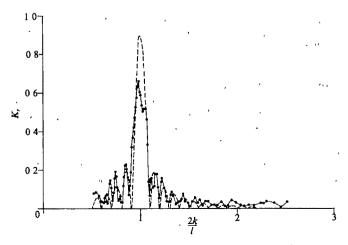

Fig. 2 Comparisons of measured (\bullet) and predicted values (---) of the reflection coefficient, K_r , as a function of the wavenumber ratio 2k/l, for b/h = 0.16 and m = 10 bars.

in such a way as to give surface elevation data every 0.25 m and to determine how wave reflection varied throughout the tank, first from the barred test section and finally from the beach. The remaining gauge was positioned at the end of the tank at the foot of the beach. These experimental arrangements are illustrated in Fig. 1.

With the bar wavelength, L_b , fixed at 1 m, incident surface water wavelengths were varied over a range giving $0.5 \le 2k/l \le 2.5$, by varying the wave period in steps of 0.01 s. For the results shown here, water depths were varied to give bar amplitude—water depth ratios, b/h, in the range $0.08 \le b/h \le 0.16$. Thus, good resolution, in non-dimensional wavenumber space 2k/l, of the order of 0.01, enabled detailed investigations to be made of the oscillatory nature of the wave reflection coefficient and of the resonant interaction peaks. These tests were carried out using small amplitude monochromatic waves only and with wave steepness values which complied with the scaling laws given by Davies and shown previously.

For surface water wavelengths approximately twice the bar wavelength, strong resonant interactions were observed leading

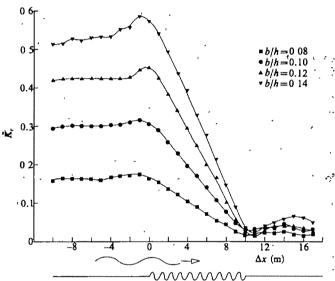

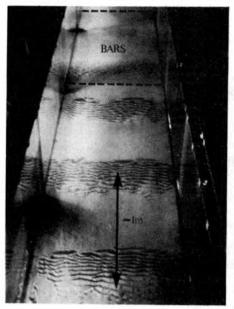

Fig. 3 The reflection coefficient, K_r , as a function of distance along the wave tank, Δx , and different ratios of bar amplitude to water depth, b/h, for m=10 bars. Note that the origin is taken as the position of zero elevation of the first bar and that $K_r \to K_r$ for $-\Delta x/h > 10$.

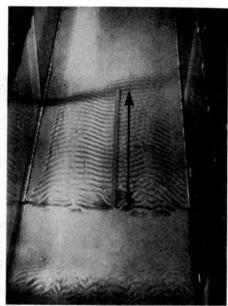

to large reflection coefficients (in some cases as large as $K_r = 0.8$) and dramatic standing or partial standing wave patterns on the up-wave side of the bars. On the down-wave side of the bars the standing wave pattern gave way to progressive waves leaving the test section and travelling towards the wave absorbing beach.

Figure 2 shows the variation of wave reflection coefficient, K_r , with the wavenumber ratio 2k/l for 10 bars and a bar amplitude-water depth ratio of b/h = 0.16 (h = 31.3 cm). Also shown are the first-order predictions from Davies^{1,2}, uncorrected for the effects of wave attenuation as the incident waves propagate over and are reflected by the bars. If the theoretical results are corrected by the method proposed by Davies¹, to relax the condition $|a_r/a_i| \ll 1$ and to give a more realistic result allowing for wave attenuation, the predicted peak value of K_r at $2k/l \approx 1$ is $K_r = 0.75$, which is in quite close agreement with the measured value.

A striking feature of these results is the large resonant interaction peak at $2k/l \approx 1$, with peak reflection coefficients of ~ 0.65 , and the oscillatory nature of K_r in respect of 2k/l. Figure 3 shows the results from measurements of the reflection coefficient at resonance, at different positions, Δx , along the tank and throughout the barred test section. Note that this is a modified reflection coefficient K_r , such that $K_r \to K_r$ for $-\Delta x/h > 10$. Measurements are shown for bar amplitude—water

Fig. 4 Left, ripple patches with a 1-m spacing formed beneath a partial standing wave on the up-wave side of 2×1 m wavelength bars. The bar amplitude is 5 cm and for these observations the water depth was 15.6 cm and the reflection coefficient was $K_r \approx 0.34$. The largest ripples were ~1.5 cm high with wavelengths of about 5.5 cm. Right, a continuous sheet of ripples formed down-wave of the reflecting bar system. Ripple heights were of the order of 1.0-cm with wavelengths of about 4 cm.

depth ratios in the range $0.08 \le b/h \le 0.14$ that is $35.7 \le h \le$ 62.5 cm. The resonant wave periods varied from 1.17 to 1.28s. dependent on actual water depth, and were usually within 0.02s of the predicted values. These results indicate that on the up-wave side of the bars the reflection coefficient, $K_r \rightarrow K_r$, is more or less constant and rises to a peak value within a few water depths of the bars before falling, linearly throughout the test section, to values of order 0.05 or less, which is the reflection from the beach alone. While only preliminary measurements for 10 bars are shown here, later measurements on 4, 2 and 1 bars have shown similar trends to those given in Figs 2 and 3. These and other observations are to be reported more fully elsewhere.

Davies^{1,2} has suggested that as a result of the partial standing wave which forms up-wave from a reflecting bar system, the pattern of wave orbital motions near the bed may lead to areas of preferential erosion and deposition of sediment. Potentially, at least, this provides a mechanism for bars to grow in the up-wave direction.

To confirm this result fine sand of about 235-µm mean diameter was sprinkled in a thin uniform layer throughout the barred test section (with 2 bars only) and for about 2-3 m on either side of it. Waves were started from rest and the wave amplitude increased until sediment motion was initiated. Sediment movement was then observed for a resonant wave reflection condition $(K_r \approx 0.34)$ and the evolution of ripple patches recorded on the up-wave and down-wave side of the bars. Figure 4 shows results from these experiments. The important features are the formation of ripple patches with a 1-m spacing on the up-wave side of the bars (Fig. 4a) and the appearance of a more or less continuous sheet of ripples on the down-wave side (Fig. 4b). Both these features are associated with a 2-m surface wavelength. In Fig. 4a erosion and ripple formation was observed to occur beneath the nodes of surface elevation of the partial standing wave. With increasing time ripple heights were observed to grow on the up-wave side of each patch in such a way as to bring about an accumulation of material approximately midway between node and antinode and roughly in the position where bar crest formation would be expected to occur. These results confirm that a potential bar-growth mechanism occurs up-wave of the bars (Fig. 4a), but not on the down-wave side (Fig. 4b), and while these results cannot be extended unambiguously to the case of naturally occurring sand bars on an erodible bed, there is strong evidence to suggest that such a mechanism may occur in practice. Note that Nielsen4 also found evidence of bar growth beneath standing waves (not generated by bars) and in particular that fine sand (80 µm), moving mainly in suspension, accumulated

directly under the antinodes. The results described here are for coarser material moving principally as bedload and the resulting distribution of sediment is governed more by velocities near the bed and less by the convection cells described by Nielsen.

I thank the Commander and Director of the US Army, Corps of Engineers, Coastal Engineering Research Center, Fort Belvoir, Virginia, USA, for experimental facilities, and also Dr A. G. Davies for valuable discussion.

Downcore variation in sediment organic nitrogen

John Berton Fisher* & Gerald Matisoff

Department of Geological Sciences, Case Western Reserve University, Cleveland, Ohio 44106, USA

W. J. Lick

An historical record of natural (pre-cultural) and anthropogenic (influenced by man's activities) chemical inputs to the environment is contained in accumulating sediment deposits and is commonly expressed as a depositional flux1. This flux is traditionally calculated as the product of the sediment accumulation rate and the concentration of a substance in the sediment1. Previous work has quantified depositional fluxes of metals and nutrients by assuming that the vertical distribution of these substances in sediments is unaffected by post-depositional migration, chemical reaction or porosity variations²⁻¹⁰. We present here a procedure for calculating the historical depositional flux (loading record) of a substance which undergoes post-depositional chemical reaction in a compacting sediment column. The method is demonstrated by calculating the loading record of organic nitrogen at one locality in Lake Erie.

^{*} Present address: Amoco Production Company, PO Box 591, Tulsa, Oklahoma 74102, USA.

Organic nitrogen was selected for study because its vertical distribution in Lake Erie sediments (41°42.0′ N; 82°18.8′ W) depends solely on the depositional flux of particulate organic nitrogen and the post-depositional rate of microbial decomposition of organic nitrogen; nitrogen does not participate in mineral equilibrium reactions in Lake Erie sediments. Microbial degradation of particulate organic nitrogen compounds converts their contained nitrogen directly to ammonium¹¹. We have assumed that the destruction of particulate organic nitrogen may be quantified by measuring net ammonium production. Because some of the produced ammonium may be converted to other nitrogen species, the assumed rate of decomposition of particulate organic nitrogen is a minimum. As a result, the calculated loading record for organic nitrogen represents the minimum organic nitrogen loading record at this locality.

The rate of nitrogen loss from sediment solids (or gain by interstitial water) is proportional to the concentration of particulate organic nitrogen present¹¹⁻¹³. This is illustrated with data from the Lake Erie study site in Fig. 1. At any depth z (measured positively downwards) this may be expressed as

$$R(z) = -k(z)N_{P}(z) \tag{1}$$

where $N_{\rm P}(z)$ is the concentration of particulate organic nitrogen at depth z (mol N per mass sediment particles), k(z) is the apparent rate 'constant' (time⁻¹) at depth z, and R(z) is the rate of ammonium production at depth z. Note that k(z) is not a constant. It is a function of the nature of the particulate organic nitrogen undergoing decay, and, consequently, depth in the sediment. In addition, k(z) represents the resultant of many chemical reactions. Nevertheless, it is convenient to think of k(z) as an apparent integrated rate constant at depth z. It is implicitly assumed that all particulate organic nitrogen present can be utilized by bacteria. The continuity equation describing the change in nitrogen content in a mass of sediment particles travelling downward from the sediment—water interface is

$$\frac{\mathrm{d}N_{\mathrm{P}}}{\mathrm{d}t}(z,t) = \frac{\partial N_{\mathrm{P}}}{\partial t} + \omega(z)\frac{\partial N_{\mathrm{P}}}{\partial z} = R(z) \tag{2}$$

where $\omega(z)$ is the downward velocity of sediment particles at depth z due to sedimentation. ω is given by

$$\omega(z) = q/\rho(z) \tag{3}$$

where q (assumed constant) is the mass flux of sediment particles to the sediment-water interface (mass/area/time) and $\rho(z)$ is the mass of sediment particles contained in a volume of sediment at depth z:

$$\rho(z) = \rho_s(1 - \phi(z)) \tag{4}$$

where ρ_* is the density of sediment particles and $\phi(z)$ is the ratio of void volume to total sediment volume at depth z. Assuming a constant flux of particles to the sediment—water

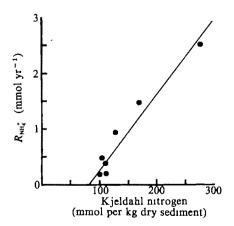

Fig. 1 Rate of ammonium production versus Kjeldahl nitrogen for sediments from the Lake Erie locality. Data from ref. 13.

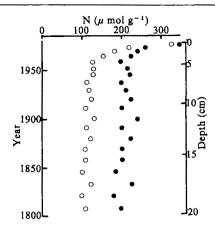

Fig. 2 Present-day particulate organic nitrogen concentration (N_P, \bigcirc) and calculated particulate organic nitrogen concentration at the time of deposition (N_{PO}, \bullet) plotted against depth and time of deposition at the coring locality.

interface and steady-state compaction, the solution to equations (1)-(4) is

$$N_{\rm P}(z,t) = N_{\rm po} \exp\left[-\frac{1}{q} \int_0^z k(z) \rho(z) \,\mathrm{d}z\right] \tag{5}$$

where t =present time and

$$N_{\rm po} = N_{\rm P} \left(t - \frac{1}{q} \int_0^z \rho(z) \, \mathrm{d}z \right)$$

 $N_{\rm po}$ is the concentration of particulate organic nitrogen at the time of deposition. The historical record of $N_{\rm po}$ can be calculated using equations (1) and (5). Measured values of $N_{\rm P}(z)$ (as total Kjeldahl nitrogen), R(z) (as ammonium production)¹³, $\phi(z)$ (calculated from water content and $\rho_{\rm p}$), and q (by ²¹⁰Pb; q=0.077 g cm⁻² yr⁻¹) (J. A. Robbins, personal communication) were used in the calculation. The values of R(z) represent net rates for ammonium production. Conversion of produced ammonium to other nitrogen species or adsorption onto sediment particles¹⁴ were not accounted for in the production rate experiments. The results of this calculation are shown in Fig. 2 along with the measured present day concentration of particulate organic nitrogen, $N_{\rm P}$.

The data presented in Fig. 2 indicate that the loading of particulate organic nitrogen to sediments at the coring locality has increased since ~1950. Scatter in the data preclude a detailed examination of particulate organic nitrogen flux before this date. The results are in reasonable temporal agreement with estimates of phosphorus input to Lake Erie¹⁵. In the early nineteenth century (1820-60), the flux of particulate organic nitrogen qN_{po} was ~0.165 mol m⁻² yr⁻¹. In the recent past (1974-77), the flux of particulate organic nitrogen was ~ 0.285 mol m⁻² yr⁻¹. This gives a current ratio of anthropogenic to natural nitrogen loading of ~0.73. This result is substantially less than estimates of this ratio made by Kemp et al.5. These workers calculated the average present ratio of anthropogenic to natural nitrogen loading to Lake Erie sediments as ~1.79 ± 0.78. They did not consider decomposition of organic matter containing nitrogen. In fact, the values of N_{ro} calculated here are minima. The rates of ammonium production used do not include any conversion of ammonium to nitrate or nitrogen gas. Further, loss of particulate organic nitrogen due to oxygen and nitrate reduction in the uppermost portion of the sediment column is completely neglected¹³. Inclusion of these reactions would increase N_{po} and lower the anthropogenic to nitrogen loading ratio. The omission of the decomposition of particulate organic nitrogen in the calculation of organic nitrogen loading to sediments will increase the apparent ratio of anthropogenic to natural nitrogen loading. For example, the application of the methodology used by Kemp et al.5 to our organic nitrogen data yields a current anthropogenic to natural nitrogen loading ratio of 1.99. The neglect of organic decomposition in estimates of

man's effect on the lake's nitrogen budget increases the apparent anthropogenic contribution by ~ 2.7 times.

The method outlined above for incorporating decomposition should be tested at other sites and, with appropriate modifications, applied to other reactive components such as phosphorus and carbon. This approach could produce significantly different nutrient budgets in many environments and may lead to a reevaluation of some management criteria.

Eocene to Oligocene benthic foraminiferal isotopic record in the Bay of Biscay

Kenneth G. Miller* & William B. Curry†

- * Oceanographic Institution/Massachusetts Institute of Technology Joint Program in Oceanography, Woods Hole, Massachusetts 02543, USA
- † Department of Geology and Geophysics, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

We present here oxygen and carbon isotopic records of Eocene to Oligocene benthic foraminifera from two Bay of Biscay Deep Sea Drilling Project (DSDP) sites (119 and 401). δ^{18} O of benthic foraminifera increases 1.9% from a middle Eocene minimum (Zones P10-P11) to an earliest Oligocene maximum (Zone NP21). Approximately 1.4% of the increase in benthic foraminiferal δ^{18} O occurs during the late Eocene to earliest Oligocene (Zones P15/16-NP21). Previous results from other North Atlantic DSDP sites (400A and 398) have significantly lower δ^{18} O values of benthic foraminifera, some by as much as 2% (refs 1-3). We believe that these differences result from diagenetic alteration of the sediments in the deeper-buried Sites 400A and 398.

Previous reports of Pacific and Southern Ocean DSDP sites noted that a 1.0-2.0% enrichment of ¹⁸O occurs from the middle Eocene to early Oligocene in both planktonic and benthic for a minifera and that $\sim 1\%$ of this change occurs near the Eocene-Oligocene boundary⁴⁻⁹. Eocene to Oligocene δ^{18} O records from three DSDP locations depart from this general Pacific-Southern Ocean trend: (1) in the Philippine Sea (Site 292) the ¹⁸O enrichment occurs only in benthic foraminifera⁹; (2) in the South Atlantic (Site 357), an isotopic enrichment occurs between the middle and late Eocene¹⁰; and (3) in the North Atlantic (Site 398) the magnitude of the isotopic increase is twice that noted in the Pacific and Southern Oceans and the enrichment occurs near the middle/late Eocene boundary^{1,2}

The Eocene to Oligocene oxygen isotopic enrichment in the North Atlantic is poorly documented. Strong diagenetic effects on isotopic composition were noted in sites drilled in the Bay of Biscay (Site 400A) (refs 1, 3, 11) and off Portugal (Site 398) (refs 1, 2, 12, 13). Eocene benthic foraminiferal δ^{18} O values are low and calculated palaeotemperatures are correspondingly high (~17°C)^{1,2} relative to Pacific, Southern Ocean⁴⁻⁹, and South Atlantic¹⁰ δ^{18} O records. Such low δ^{18} O values and high inferred palaeotemperatures may result from diagenetic effects. It is necessary to distinguish between altered isotopic signals and original unaltered signals to determine abyssal palaeocirculation patterns.

We analysed the oxygen and carbon isotopic composition of early-middle Eocene to Oligocene benthic foraminifera at two North Atlantic DSDP sites (119 and 401). We chose these sites for the shallow burial depth of their Eocene sediments (~100-400 m) versus Sites 400A and 398 (~550-600 m). Late Eocene sediments are missing from Site 119. However, drilling at nearby Site 401 recovered a relatively complete Eocene section, but no Oligocene section¹⁴. Site 119 was drilled in 4,447 m of water on Cantabria Seamount¹⁵. Using the backtracking

ocean²³⁻²⁶. Although Cibicidoides species apparently secrete their tests lower in δ^{18} O than values calculated from the Epstein et al.²⁷ palaeotemperature equation, the offsets seem to be constant²³⁻²⁶. In addition, we analysed paired samples of Gyroidinoides spp. and Cibicidoides spp. from Site 119; Gyroidinoides were $\sim 0.3\%$ enriched in ¹⁸O relative to Cibicidoides. This offset is similar to differences observed between these taxa in studies of Holocene core—top sediments²⁶.

At Site 119, δ^{18} O values increase from $\sim 0.5\%$ in the early-middle Eocene (nannoplankton Zones NP13 to NP15) to $\sim 2.0\%$ in the earliest Oligocene (Zone NP21) (Fig. 1); δ^{13} C values correspondingly increase from ~ 0.4 to $\sim 1.3\%$ from the middle Eocene to earliest Oligocene. Unfortunately a 9-Myr hiatus precludes determination of the exact timing and nature of this isotopic change between the middle Eocene and earliest Oligocene in Site 119. In the Oligocene, δ^{18} O values decrease from ~ 2.0 to $\sim 1.1\%$. δ^{13} C values decrease to a minimum of $\sim 0.0\%$ in the middle Oligocene (Zones P20–P21), then increase again to $\sim 0.5\%$. At Site 401 (Fig. 1), δ^{18} O values are $\sim 0.5\%$ in the early-middle Eocene, similar to observed values in Site 119. δ^{18} O values increase $\sim 0.4\%$ in the late middle Eocene (Zone P14). A δ^{18} O increase of 0.6% occurs within the late Eocene (Zones P15/16–P17).

Combining the isotopic record of both sites (Fig. 2) suggests that a δ^{18} O increase of ~1.4% occurs from the late Eocene to earliest Oligocene in the North Atlantic. This change occurred within an interval that may be <1 Myr (that is within Zone NP21) or as much as 4 Myr (between Zones P15 and NP21; see biostratigraphic zonations Table 1). There are pitfalls in combining sites of different palaeodepths to obtain a complete record; however, δ^{18} O values obtained for Sites 119 and 401 are similar in the overlapping section (middle Eocene). The modern temperature difference between these water depths in the Bay of Biscay is <1 °C (ref. 28), equivalent to an oxygen isotopic difference of <0.25%. These reasons justify combining the δ^{18} O records of Sites 119 and 401. Although the middle to late Eocene record may be found entirely within Site 401, the nature and timing of the δ^{18} O shift near the Eocene-Oligocene boundary involves comparing records from two different sites, and should be considered as preliminary. The Eocene-Oligocene interval in the North Atlantic is usually

discontinuous^{29,30}, and a complete Eocene to Oligocene isotopic record from one site is not available at present.

The δ^{18} O records of Sites 119 and 401 apparently correlate with isotopic records from the Pacific and Southern Oceans⁴⁻⁸ where an ¹⁸O enrichment occurs in the late Eocene to early Oligocene. In detail, the curves may not correlate. Keigwin⁹ showed that the ¹⁸O enrichment occurs in the Pacific above the Eocene-Oligocene boundary, while in our record the change occurs from the late Eocene to earliest Oligocene. However, given the errors of the biostratigraphic age assignments, we consider that the enrichments may be synchronous. Further biostratigraphic studies are needed to determine if the enrichments are diachronous or synchronous.

Although the δ^{18} O values we report are similar to values obtained from sites in the Pacific and Southern Oceans⁴⁻⁹, they are markedly higher than Eocene δ^{18} O values obtained from other sites in the North Atlantic¹⁻³ (Fig. 3). In the Eocene, benthic foraminiferal δ^{18} O in Sites 400A and 398 are as much as 2% lower than in Sites 119 and 401 (Fig. 3). Such implied differences in bottom water temperature (8 °C) between sites of similar palaeodepth (for example, Sites 400A and 119) within the small basin of the Bay of Biscay are oceanographically unreasonable. As the total range of δ^{18} O values for benthic foraminifera within any Recent core-top sample²³⁻²⁶ or Palaeogene sample¹⁰ is <1%, the 2% difference probably cannot result from sampling biases caused by selective dissolution or analysis of mixed benthic foraminiferal assemblages. However, the low values δ^{18} O observed can result from diagentic alteration of the foraminiferal test at high temperatures associated with great burial depth^{2,13}. While simple addition of calcite overgrowths of the test would be sufficient to lower δ^{18} O values, recrystallization of the foraminiferal calcite is necessary to produce both the similar δ^{18} O values of planktonic and benthic foraminifera in the Eocene of Sites 400A and 398 and the high bottom water temperatures (~17 °C) calculated for these sites¹⁻³. At Site 401, δ^{18} O of planktonic foraminifera are substantially lower than benthic foraminifera3, supporting the idea that this site is not substantially affected by diagenetic alteration. Similarly, planktonic foraminifera have substantially lower δ^{18} O composition than benthic foraminifera in the Oligocene of Site 119; due to dissolution, sufficient planktonic

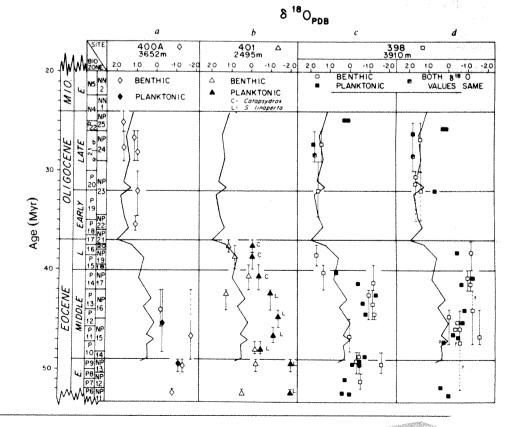

foraminifera were not available for isotopic analyses of the Eocene of Site 119.

Limits can be calculated for the abyssal temperature change in the Bay of Biscay. Shackleton and Kennett⁶ estimated that δ^{18} O of seawater before the formation of the present ice sheets was -1.2% (PDB). Assuming that Cibicidoides precipitates CaCO₃ 0.65% lower than equilibrium²⁶ and that there was no significant glacial ice buildup, the increase in benthic foraminiferal δ^{18} O from Sites 119 and 401 corresponds to a maximum decrease of bottom-water temperatures from 8 to 2 °C between the middle Eocene and early Oligocene. Alternatively, assuming glacial buildup equivalent to the present ice sheets, the increase represents a minimum change in bottom-water temperature from 8 to 6 °C.

The benthic temperature drop in the late Eocene to early Oligocene in the Pacific and Southern Oceans has been attributed to the first formation of bottom waters in the Antarctic region⁷; however, the North Atlantic basins may have had a different source of cold bottom water. Seismic stratigraphical evidence from the northern North Atlantic Ocean indicates that northern sources of vigorously circulating bottom water began in the late Eocene to early Oligocene^{30–32}. Miller and Tucholke³⁰ suggested that this bottom water was of Arctic origin and that it flowed through the Norwegian–Greenland Sea, the Faeroe–Shetland Channel, and possibly through the Denmark Straits into the North Atlantic.

The isotopic changes observed in Site 119 correlate with a change from a benthic foraminiferal assemblage dominated by Nuttallides truempyi to an assemblage dominated by N. umbonifera (Fig. 1); however, the hiatus prevents an exact determination of the timing of this faunal change. Within the Oligocene, N. umbonifera reaches a peak in abundance correlating with a δ^{13} C minimum. As N. umbonifera is negatively correlated with carbonate saturation in the modern ocean³³ and lower δ^{13} C values are often associated with older water masses³⁴⁻³⁶, we speculate that the isotopic and faunal records of Site 119 reflect a change from younger, less corrosive water in the early Oligocene to older, more corrosive bottom water in the middle Oligocene. The change from lower carbon and oxygen values in the Eocene to higher carbon and oxygen values in the earliest Oligocene may reflect a change from older and

Fig. 3 Comparison of previously reported1 Eocene to Oligocene O values for benthic and planktonic foraminifera from North Atlantic DSDP sites. Combined oxygen isotopic curve obtained from Sites 119 and 401 is superimposed on each (solid line). Columns a and b are from Bay of Biscay Sites 400A and 401, respectively. Columns c and d are from Site 398 off Portugal: c represents ages assigned using cal-, d repcareous nannoplankton resents the same data with ages assigned using planktonic foraminifera³⁸. Biostratigraphic ages for Sites 400A and 401 have been assigned using planktonic foraminifera 14 and nannoplank-. Error bars indicate length of biostratigraphic zone(s) to which the sample has been assigned; they have been omitted for clarity from planktonic foraminiferal δ^{18} O values in columns c and d.

warmer Eocene bottom water to colder, younger, more vigorously circulating bottom waters of northern origin in the early Oligocene.

Compound eyes project stripes on the optic tectum in Xenopus

J. W. Fawcett & D. J. Willshaw

National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, UK

In the vertebrate nervous system it is commonly found that when two similar nervous structures innervate a third, each innervating structure colonizes distinct areas of the target in a striped manner. Much of our knowledge of the rules of neuronal connectivity derives from the study of the development of the frog visual system, which has the advantages of being simple, and accessible throughout embryonic development. When two separate eyes are made to innervate a single frog optic tectum, the two projections separate into stripes, reminiscent of the ocular dominance stripes of the mammalian visual cortex1. We report here an experiment in which the projection from a single eye, surgically constructed in the embryo out of two matching half-eyes (a 'compound' eye), separates out into stripes. The observation that a single eye can produce a striped projection rules out many hypotheses of how stripes are formed, and provides evidence that the formation of an ordered projection on the optic tectum requires the operation of two separate machanisme

In lower vertebrates, for which much is known of the mechanisms of neural connectivity^{2,3}, the retinotectal projection is completely crossed, and direct binocular innervation occurs by a secondary pathway⁴. Experimental manipulation is therefore needed to induce two retinae to innervate the same target. It is then found that the tectum is divided up between the fibres from the two eyes, in some cases to form eye-specific patches. and in others stripes⁵⁻⁹. In order for stripes to form, there must be some means of distinguishing the fibres from one retina from those from the other; three possible mechanisms come to mind. (1) Fibres carry a record of their side of origin, which enables those from a left eye to be distinguished from those from a right eye. The same effect would be produced if the positional information in the eye were carried by a varying signal such as a biological oscillator¹⁰. The two eyes could therefore be out of phase. (2) Terminal arbors are only stable on their target if neighbouring arbors are from neighbouring ganglion cells. (3) The mechanics of fibre growth are such that the fibres from two separate eyes remain segregated through to their site of termination.

There are various ways of producing double innervation of the visual centres in lower vertebrates, but to determine which of the above theories is correct, a useful technique is surgically to place together in the same eyecup of an embryonic Xenopus, two half-eye rudiments of matching retinal origin (for example, two nasal halves) to create a compound eye11. This results in a retinotectal map in which each of the two half-eyes projects across the entire tectum, superimposed on each other, and with corresponding retinal positions of origin mapping to the same area of tectum. In Xenopus the operation is done before any nerve fibres have grown out of the eye, and there is therefore minimal disruption of the normal development of the visual system; the fibres follow the normal pathway to the brain. This also allows the full development of the projection to be studied, and its topography can be assessed electrophysiologically, so that the relationship between the mechanisms of map-making and stripe formation can be studied.

Compound eyes were made by standard procedures¹¹. One half of the eye rudiment of a stage 29-31 Xenopus embryo was replaced with the opposite half from another embryo of the same age, so that the eye had two nasal halves (NN), two ventral halves (VV) or two temporal halves (TT). The donor half was from the opposite side of the head. Three of the animals also had the other eye removed. The animals were reared for 1-2 months after metamorphosis, then the projections made by the compound eyes were assessed.

The success of the compound eye operations was confirmed by electrophysiological mapping. The retina was then lesioned near the optic nerve head so as to cut most of the fibres from either the host or donor half, and a ~20% solution of horseradish peroxidase (HRP) was then injected over the lesion. After 48 h, the animal was anaesthetized, then perfused and fixed in 2.5% glutaraldehyde in 0.1 M phosphate buffer. The brain was removed and processed using the method of Adams¹² with the following modifications: incubation was in 1% CoCl₂ for 1 h, then in diaminobenzidine acid solution for 90 min, followed by the addition of $0.3\%~H_2O_2$ (4 ml per 100~ml) at $0~^{\circ}C$ for 20~min. The brains were cleared in methyl salicylate, and examined as whole mounts. A total of 11 animals were examined, of which 9 had both good maps and HRP fills.

Electrophysiological mapping was carried out using standard techniques. In all cases the maps obtained were of the classical compound-eye type^{11,13}. Most of the recording positions produced responses that could be driven by two distinct areas of the visual field. These areas were so arranged that (1) each of the constituent halves of the compound eye projected over the entire tectum in such a way that areas of retina of similar origin projected to the same area of tectum, and (2) the orientation of each map was that predicted if the appropriate half-eye were part of a normal eye.

In all cases the neuropil was labelled discontinuously. The neuropil was fairly superficial, and fibres of passage were seen

at the same depth and deeper than it. In eight of the nine cases the tectum was striped. Typically there were four or five labelled areas. As measured in the cleared preparations, the stripes were of constant width (60-80 µm) and there was a constant interstripe distance of 60-80 µm. The stripes ran rostrocaudally in all cases, and were usually straight, or sometimes slightly wavy. In some cases the stripes coalesced at one extremity of the tectum. This could have been due either to the HRP leaking into the half-eve that it was not intended to fill, or to the mechanism of stripe formation (see below). The actual part of the tectum that was covered depended on the class of compound eye, since the area immediately surrounding the optic nerve head projects to different tectal areas in different classes of compound eye, and it was not possible to fill the chosen half-eye right up to the optic nerve head. Thus in the NN preparations there was no filling of neuropil at the front of the tectum; the midline of the NN eye projected to the rostral tectum. It made no difference to the result whether the host or donor half of the eye was filled.

Optic fibres followed the normal route to the brain, and the manner of their delivery to the tectum was characteristic of the pathways of the various types of compound eye (refs 14, 15 and J.W.F. and R. M. Gaze, in preparation). The only structure that showed striping was the neuropil; the fibres running to the areas of neuropil formed an even sheet over the tectal surface, with no evidence of being divided into separate bands each heading to a specific stripe. No stripes were observed in the optic tract. In addition, fibres of passage were seen between the stripes. In the NN preparations, these fibres ran rostrocaudally, as did the stripes (Fig. 1). In the case of the VVs, however, the fibres ran across the tectum in a rostro-medial to caudo-lateral direction, having all arrived at the tectum by the medial brachium of the tract. The stripes, however, still ran rostrocaudally (Fig. 2). The pretectal nucleus, neuropil of Bellonci and basal optic nucleus, where filled, showed no striping.

In our preparations the fibres from the two half-retinae making up the compound eye travel in a single optic nerve along a normal pathway to the optic tectum. Stripes are visible only in their terminal arborizations. This rules out any mechanism relying on fibres maintaining contact with their original neighbours throughout the optic pathway; nor can stripes be due to the fibres from one eye taking an abnormal pathway, as could be the case in 'three-eyed' frogs⁷. Our experiment also rules out the possibility of stripes being due to an oscillating positional signal.

The two possible mechanisms remaining, therefore, are that either left and right eyes carry specific labels, or that there is a mechanism which stabilizes arbors that are neighbours on the

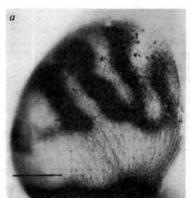

Fig. 1 a, Dorsal view of a whole mount of a tectum innervated by a double nasal eye: medial tectum to the right, caudal to the top. The donor half of the eye was filled with HRP. Stripes run rostrocaudally; the fibres running to them are unstriped. Scale bar, 200 μm. b, Detail from a. Fibres of passage can be seen running between and below the stripes. Scale bar, 100 μm.

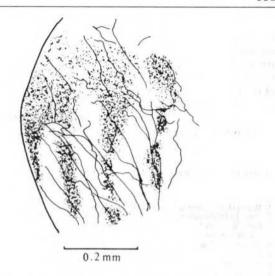

Fig. 2 Camera lucida drawing of a whole mount of a tectum innervated by a double ventral eye. Orientation as in Fig. 1. The stripes again run rostrocaudally, but the fibres to them run from rostro-medial to caudo-lateral tectum.

tectum, and whose retinal ganglion cells are also neighbours. The data of Law and Constantine-Paton⁹ make the first possibility unlikely, but we are testing this by constructing compound eyes in which both halves are from the same side of the head. The second mechanism would result in stripes coalescing in the region to which the retinal midline projects; our results provide some evidence for this.

The neurophysiological and neuroanatomical evidence strongly suggests that the mechanism responsible for the orientation and internal ordering of the retinotectal map in amphibia depends on a set of labels encoding retinal position^{2,3,16}. This allows, for example, fibres from two originally nasal poles of a double nasal eve to project to the same area of tectum. The presence of stripes, however, seems a direct contradiction of this; the two sets of fibres are directed to the same area of tectum only to be separated again. It seems probable, therefore, that the retinotectal map forms in two stages: first the ingrowing optic fibres are guided to terminate on an area of tectum which is determined by the positional labels carried by the retinal ganglion cells from which they came. Once on the tectum, the fibres produce terminal arborizations which interact according to a different set of rules, as discussed above; in doubly innervated tecta this results in the formation of stripes. This is consistent with the suggestion that stripes develop from an initially diffuse projection8. It would certainly require less rearrangement of fibres to produce stripes from a retinotopic map than retinotopy from a striped but disordered one.

In normal development, we believe that the map orientation and a rough degree of retinotopic order are defined by the pathways which fibres follow in growing on to the tectum. Interactions between neighbouring arbors of the type that lead to stripe formation on doubly innervated tecta refine the map and allow it to accommodate to the arrival of new fibres and the growth of the tectum. These two mechanisms correspond to the division suggested by Law and Constantine-Paton⁸.

The stripes in our preparations always ran rostrocaudally. This orientation is clearly not determined by the direction of ingrowth of the optic fibres, as when this is altered (as in the VV animals), the stripes still run rostrocaudally. The most obvious explanation for the direction is that it reflects the mode of growth of the tectum, which grows from its caudal margin¹⁷. Thus, patches of fibres from the two half-eyes formed when the tectum is very small might be expected to extend caudally as the tectum grows. In *Xenopus*, when two optic nerves are induced to innervate a fully grown tectum by regeneration (ref.

6 and D.J.W. and R. M. Gaze, in preparation), the regions of tectum innervated by one eye are not stripes but patches, with no discernible orientation. This may reflect the fact that the tectum is already fully grown and the initial regenerated projection is disorganized¹⁸. It is interesting that the constant width of the stripes corresponds approximately to the size of the optic fibre arborizations on the Xenopus optic tectum 19,20

We thank R. V. Stirling for developing the method of HRP staining and Liz Hirst for histological assistance.

Adhesion-dependent heparin production by platelets

Simonetta Vannucchi, Gabriella Fibbi, Franca Pasquali, Mario Del Rosso, Renzo Cappelletti & Vincenzo Chiarugi

Institute of General Pathology, University of Florence, Operative Unit No 10, CNR Special Project 'Control of Neoplastic Growth', Via Morgagni 50, 50134 Firenze, Italy

It is well known that platelets are involved in blood clotting. In addition, substances of the platelet granules or on the platelet surface cooperate with plasma and vessel wall components to modulate control of haemostasis1. Here we provide evidence that platelets adhered to a substrate can release heparin.

When fresh human platelets were isolated from plasma and incubated in vitro in suspension or allowed to adhere to a solid surface, the medium of adherent cells showed an anticoagulant activity that was absent in the medium of suspended cells. As shown in Table 1, the production of the activity is adhesion dependent but does not require a specific adhesion substrate; however, artificial rafts containing compounds found in the subendothelial basal lamina were more effective than plastic or glass surfaces in inducing the release of the anticoagulant activity. This activity is resistant to heat, proteolysis, hyaluronidase and chondroitinase, is sensitive to nitrous acid, retained by anionic exchangers and eluted by cationic exchangers.

Figure 1a shows the electrophoretic analysis of platelet glycosaminoglycans. Chondroitin 4-sulphate is the only glycosaminoglycan present in suspended platelets, with sialosaccharides and trace amounts of dermatan sulphate. In contrast, in adhesion conditions, a complex pattern of glycosaminoglycans is present, the bands being identified as chondroitin 4-sulphate, sialosaccharides, dermatan and heparan sulphates

Table 1 Anticoagulant activity of media from platelets incubated in different conditions and sensitivity to various degradative agents

Culture conditions	Thrombin time (s)
No platelet	20/11
Suspended platelets	
Platelets adherent to glass, plastic or	
polyvinylchloride	120/150
Platelets adherent to artificial rafts containing	
type IV collagen, fibronectin and laminin	160/200

Type of degradation or treatment on glass-adherent platelet medium

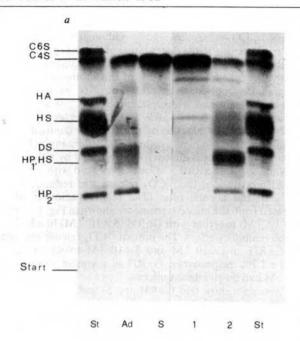

Exhaustive proteolysis, chondroitinase ABC, testicular hyaluronidase, heat (10 min at 100 °C) 120/160 passage through AG 50 X8 Nitrous acid, passage through AG 1 X2 30/40

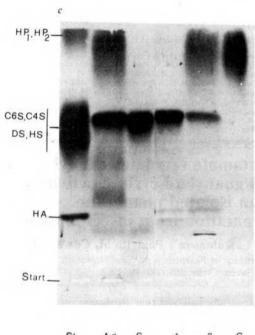

Platelets were isolated from pooled human blood containing either EDTA (0.1%) or sodium cytrate (0.38%) as anticoagulant. The blood was allowed to sediment spontaneously at room temperature and the upper phase was centrifuged at low speed (10g for 10 min). The supernatant was centrifuged at 1,000g for 2 min to sediment residual leukocytes and the platelets were then sedimented from the second supernatant by prolonged low-speed centrifugation (30 min at 160g). Leukocyte contamination was less than 1% as checked with the light microscope after May-Grunwald-Giemsa staining. Platelets were suspended in Hank's saline containing 1 mg ml⁻¹ glucose; the concentration was 3×10^8 cells per ml for the suspension experiments and 10-fold diluted for adhesion experiments. Cells were layered on a solid surface with a ratio of 3×10^6 cells per cm² and allowed to adhere to the substrate for 15 min. At the end of this incubation up to 60% of the cells were adherent. The medium was collected and centrifuged to remove non-adherent platelets. Artificial collagen rafts containing basement membrane non-collagenous proteins were prepared according to Rubin et al.3. All the matrix compounds were a gift of Dr R. Timpl. The media were concentrated 40-fold by ultrafiltration on Amicon apparatus equipped with a YM5 membrane and used directly for thrombin time assay. The test was carried out as follows: 100 µl of plasma pool were incubated at 37 °C with an equal volume of the tested sample, 100 µl of a thrombin solution (Boehringer-Mannheim) were added and the coagulation time was measured. Alternatively, media were digested with papain (0.1 mg ml⁻¹) at 60 °C for 48 h in the presence of 5 mM β -mercaptoethanol at neutral pH. After heating for 1 h at 95 °C to inactivate the protease, various aliquots were treated with hyaluronidase, chondroitinase or nitrous acid as described elsewhere After dialysis and concentration to the original volume, the processed samples were again assayed for anticoagulant activity by the same test. Aliquots were passed through cationic or anionic exchangers (Bio-Rad), neutralized, dialysed, concentrated to the original volume and tested for the anticoagulant activity.

Table 2 Pulse labelling of platelet glycosaminoglycans

Compound	C4S	HS/DS	HP
Densitometric value of the electrophoretic band (A units) H-glucosamine (c.p.m.) S-inorganic sulphate (c.p.m.)	0.37	0.15	0.32
	9	134	313
	7	49	127

Adherent platelet medium was added with $1\,\mu\text{Ci}\,\text{ml}^{-1}$ of $^3\text{H-glucosamine}$ and $5\,\mu\text{Ci}\,\text{ml}^{-1}\,^{35}\text{S-inorganic sulphate (NEN)}$ and the cells were incubated for 30 min Glycosaminoglycans were isolated as described in Fig. 1 legend, subjected to electrophoresis at pH 5.0 and densitometrically recorded. The cellulose acetate was cut into strips corresponding to the well resolved bands of chondroitin 4-sulphate (C4S) and heparin (HP) and the less resolved bands of heparan and dermatan sulphates (HS/DS). The acetate strips were then counted in a Bray's scintillation mixture.

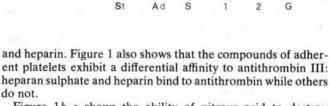

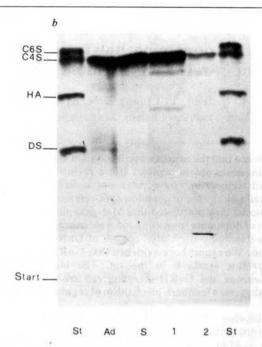

Figure 1b, c shows the ability of nitrous acid to destroy heparan sulphate and heparin as well as the high sulphate content of heparin. Commercial and platelet heparin was diluted to obtain solutions producing the same slowing effect on the thrombin time assay and the same volume of these solutions was then run on electrophoresis, stained and recorded by densitometry. A comparison of the peak areas showed anticoagulant activity of platelet heparin to be higher than that of the commercial standards.

When adherent cells were pulse labelled with radioactive precursors (see Table 2), chrondroitin 4-sulphate took up almost no label whereas the other compounds, particularly heparin, were labelled by both radioactive glucosamine and sulphate, suggesting synthesis or a post-synthetic processing of N-sulphated glycosaminoglycans.

a, Electrophoresis of glycosaminoglycans extracted from the media of adherent and suspended platelets. Electrophoresis was on cellulose acetate at pH 5.0 according to Cappelletti et al.⁵. b, Same samples as in a after direct nitrous acid treatment as described by Cappelletti et al.6, to identify N-sulphated compounds. c, Same samples as in a, run at pH 1.0 according to Wessler7, to reveal the relative sulphate content. After exhaustive proteolysis with papain the media were heated for 1 h at 95 °C and centrifuged at alkaline pH to avoid the formation of complexes between glycosaminoglycans and precipitated proteins. This is a critical step to avoid a selective loss of N-sulphated compounds. Supernatants were neutralized, loaded on a column of AG 50 X8 (Bio-Rad) and eluted with distilled water to remove the non-acidic proteins. Residual acidic proteins were precipitated from the eluate with 10% trichloroacetic acid. The glycosaminoglycans were recovered from the supernatant by precipitation with 2.5 volumes of cold ethanol. Cellulose acetate electrophoresis was carried out as described elsewhere5. Glycosaminoglycans from medium of adherent platelets were loaded onto a gel of antithrombin III-substituted Sepharose 4B (Pharmacia) following the instructions of the manufacturer: 10 mg of antithrombin III (a gift of Professor B. Casu) were coupled to 10 ml of agarose. The column was washed with 50 ml (7 column volumes) of 0.1 M Tris-HCl pH 7.4; retained glycosaminoglycans were eluted with 30 ml of 1.5 M NaCl in 0.1 M Tris-HCl pH 7.4. Both elution volumes were dialysed against distilled water and freeze-dried for the analysis of glycosaminoglycans. 1, Compounds not retained by antithrombin; 2, compounds retained by antithrombin. Letters to the left refer to the bands of the standard. The bands of the biological samples were characterized as described elsewhere4. Compounds not migrating at pH 1.0 were identified as sialosaccharides on the basis of the susceptibility to neuraminidase degradation. C6S, chondroitin 6-sulphate; C4S, chrondroitin 4-sulphate; HA, hyaluronic acid; HS, heparan sulphate; DS, dermatan sulphate; HP₁, HP₂, fast-moving heparin and slow-moving heparin as described by Bianchini et al.*; St, standard mixture; G, standard heparin (Glaxo).

Platelets are known to release several clotting factors on aggregation, including fibrinogen, thrombin, coagulation factor V and the anti-heparin platelet factor IV2. The present finding provides evidence of heparin release by a major blood cell subclass, thus indicating a possible source of endogenous heparin. Furthermore, it may indicate an alternative, nonthrombogenic role for platelets in vessel wall repair and control of clotting.

Inhibition of dopamine biosynthesis by gonadotropin-releasing hormone in rat

W-K. Wang, L. S. Jeng, Y. Chiang & N. K. Chien

Biophysics Laboratory, Institute of Physics, Academia Sinica, Taipei, Taiwan 115

There is evidence that the neuroendocrine system can be modulated by endogenous opioid peptides (for a review see ref. 1). Recently Rotsztejn et al.2 have ruled out a direct effect of Met-enkephalin on release of gonadotropin-releasing hormone (GnRH). Instead they postulated that Met-enkephalin inhibits the secretion of dopamine from dopaminergic neurones thereby reducing the dopamine-stimulated release of GnRH from the hypothalamus. We report here evidence that GnRH can itself supress dopamine synthesis in the rat. The fact that the dopamine neurone and GnRH-secreting cell are adjacent to each other³ suggests a feedback mechanism of regulating GnRH release.

Sprague-Dawley rats (180-230 g) were killed by decapitation. The corpus striatum was dissected on ice and homogenized in 10 vols 0.32 M sucrose using a Teflon pestle tissue homogenizer. After centrifugation at 1,000g for 15 min, 50 µl aliquots of the synaptosome-containing supernatant were incubated with 150 µl of physiological medium containing (mM): 125 NaCl; 1.48 CaCl₂; 4.8 KCl; 2.5 MgSO₄; 22 NaH₂PO₄; 10 NaHCO₃; 16 glucose, to give a final pH of 6.6 after equilibration with 95% O_2 -5% CO_2 at 37 °C. $[1^{-14}C]$ tyrosine (specific activity 50 mCi mmol⁻¹) at a concentration of 10 μ M was added to the preparation, together with bacitracin (10⁻⁵ M) to reduce the degradation of polypeptides. GnRH, Met-enkephalin or naloxone were added to the incubation medium with 10 μl 0.1 M phosphorous buffer pH 6.6 as carrier; controls recieved the buffer alone. The method used to determine dopamine synthesis was modified from that of Weiner⁴ and Kuzcenski⁵. who measured the release of ¹⁴CO₂ from [1-¹⁴C]tyrosine. We simplified the incubation medium to mimic the cerebrospinal fluid and used a respirometer to supply oxygen and allow continuous measurement of the ¹⁴CO₂ output from the tissue⁶. Addition of iodotyrosine $(5 \times 10^{-4} \text{ M})$ to the incubation medium inhibits >90% of the ¹⁴CO₂ release⁷.

Dopamine formation was calculated when the ¹⁴CO₂ output had reached a steady state, that is, after 50 min incubation. The rate of dopamine synthesis in 10 preparations was 0.2± $0.02 \text{ mol mg}^{-1} \text{ min}^{-1} \text{ (mean} \pm \text{s.d.)}.$

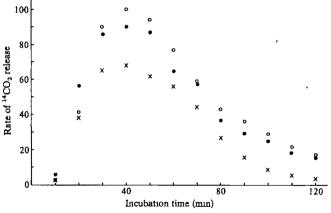

Fig. 1 Rate of ¹⁴CO₂ release from labelled tyrosine plotted against incubation time. The exponential increase in rate before 50 min of incubation is from isotopic equilibrium⁶. The rate of $^{14}\text{CO}_2$ release maintained steady-state values between 50 and 120 min of incubation. GnRH $(5 \times 10^{-6} \text{ M})$ added to the preparation (x) gave ~30% inhibition of dopamine synthesis. Naloxone at 5×10^{-6} M together with GnRH blocked 70% of this inhibition (•). O, Control.

Met-enkephalin (10⁻⁵ M) added to the incubation mixture reduced ¹⁴CO₂ release by ~40%. Although some of this inhibition could be due to the degradation of the enkephalin releasing unlabelled tyrosine, we showed by kinetic studies using added unlabelled tyrosine that >10% of this inhibition was a direct effect. Other opioid δ-receptor drugs, for example, D-Ala²-Met-enkephalin and Metkephamid⁸ at 10⁻⁵ M also inhibited dopamine synthesis by ~10% and 20% respectively and this inhibition was not blocked by naloxone. In contrast, the 11% inhibition of dopamine synthesis by sufentany¹ (10⁻⁵ M), a μ -receptor drug, was almost totally blocked by naloxone.

When GnRH (5×10⁻⁶ M) was incubated with the synaptosomal preparation, the $^{14}CO_2$ release was reduced to 73.4± 6.6% of the normal rate. (The relative amounts of $^{14}CO_2$ released from the added tyrosine are shown in Fig. 1.) Naloxone $(5\times10^{-6} \text{ M})$ together with GnRH $(5\times10^{-6} \text{ M})$ blocked ~70% of the inhibitory effect. The normal $^{14}CO_2$ release was reduced by GnRH at 1×10^{-6} M and 5×10^{-7} M to $83.1\pm3.8\%$ and $89.9\pm2.7\%$ respectively. GnRH at a concentration of $<1\times$ 10⁻⁸ M had no significant effect.

These data show that GnRH and δ - and μ -receptor opioids all have similar inhibitory effects on dopamine synthesis. We therefore postulate that GnRH exerts a negative feedback action on dopaminergic neurones, that is, GnRH inhibits it own release by inhibiting dopamine synthesis.

Glutamate regulates adenylate cyclase and guanylate cyclase activities in an isolated membrane preparation from insect muscle

Neil L. Robinson*, Paulette M. Cox & Paul Greengard Department of Pharmacology, Yale University School of Medicine, New Haven, Connecticut 06510, USA

It is generally believed that glutamate serves as a neurotransmitter at many vertebrate and invertebrate synapses. There is, however, little information concerning the possible involvement of cyclic nucleotides as intracellular second messengers for any of the postsynaptic actions of glutamate. Direct activation of adenylate cyclase has been reported for several neurotransmitters and neuromodulators¹, but no such effect has been reported for glutamate. Moreover, although several neurotransmitters including glutamate have been shown to increase cyclic GMP levels in intact preparations of nerve and muscle tissue^{2,3} apparently by promoting Ca²⁺ entry into the cells, no neurotransmitter has been shown to activate guanylate cyclase in a cell-free preparation. L-Glutamate is the prime candidate for the neurotransmitter at the excitatory neuromuscular. synapses in insects4. Moreover, recent studies have shown that glutamate application raises both cyclic AMP⁵ and cyclic GMP levels (P.M.C., unpublished observations) in insect muscle. To determine the mechanism underlying these increases, we have studied the effect of glutamate in a membrane fraction prepared from this muscle, and report here that the neurotransmitter activates both adenylate cyclase and guanylate cyclase in the membrane preparation, and that the activation by glutamate of guanylate cyclase is calcium independent.

Fig. 1 Glutamate stimulation of cyclic AMP (cAMP) and cyclic GMP (cGMP) production by a membrane preparation from the body-wall muscles of the dipteran Sarcophaga Third instar larvae of the insect were used. The central nervous system, digestive system and fat body were removed and the body-wall muscles were scraped from the cuticle and then homogenized on ice in isotonic saline (30 larvae per 25 ml) (NaCl, 120 mM; KCl, 2 mM; CaCl₂, 0.5 mM, thiourea, 1 mM; Tris-HCl, 10 mM, pH 6 8) in a Teflon/glass homogenizer (10 passes at 100 r.p.m.). The homogenate was centrifuged at 4,000g for 30 min and the supernatant was collected and centrifuged at 280,000g for 60 min. The supernatant (S2) was removed and the pellet (P2) lysed by resuspension in 25 ml of hypotonic saline (10 mM Tris, 1 mM thiourea, and either 0.5 mM CaCl₂ for 'calcium' incubations or 1 mM EGTA for calcium-free incubations). The suspension was then repelleted by centrifugation at 280,000g for 60 min. The pellet formed (P3) was resuspended in 2 ml cyclase assay buffer (10 mM NaCl, 10 mM Tris-HCl, 10 mM MgCl₂, 0 5 mM MnCl₂, 0.05 mM alanine, 1 mM thiourea and either 0.5 mM CaCl₂ or 1 mM EGTA, pH 6 8), adenylate and guanylate cyclase activities were assayed concurrently and the cyclase reaction started by the addition of an equal volume of cyclase assay buffer containing 2 mM ATP, 1 mM GTP and 2% albumin Incubations were stopped by the addition of five vol of acidified alcohol (0.5 ml M HCl in 100 ml ethanol). Samples were evaporated to dryness at 55 °C under nitrogen and then extracted in extraction buffer (10 mM Tris, 1 mM EDTA pH 6 8). Cyclic AMP was assayed by the method of Brown et al. Ocyclic GMP was assayed by radiommunoassay as described elsewhere. The protein content of samples was determined using the Lowry folin-phenol method. Each point represents the mean ±s.e.m. of at least three estimations. In control experiments it was found that calcium was required during the initial homogenization to retain cyclase activity, whereas subsequent l

Figure 1 shows the effect of various concentrations of glutamate on production of cyclic AMP and cyclic GMP by a membrane preparation of body-wall muscle from the dipteran Sarcophaga. Adenylate cyclase activity was stimulated in either the presence or absence of calcium. However, stimulation of cyclic AMP synthesis required a lower concentration of glutamate in the absence of calcium (activation occurring at a glutamate concentration >10⁻¹¹ M) than in the presence of calcium (>10⁻⁹ M glutamate). In the absence of calcium, maximal stimulation of adenylate cyclase activity was observed at ~10⁻⁹ M glutamate, inhibition occurring at higher concentrations of the neurotransmitter. Guanylate cyclase activity was also stimulated in either the presence or absence of calcium, maximal stimulation being observed at 0.1 µM glutamate in both cases. The similarity of the dose-response curves as a function of glutamate concentration in the absence and presence of calcium (Fig. 2) indicate that this enzyme activity can be stimulated by either of two mechanisms, one of which is glutamate dependent and calcium independent, the other being calcium dependent and glutamate independent.

The fact that very low concentrations of glutamate are effective in stimulating adenylate cyclase and guanylate cyclase activities suggests that these intracellular messenger systems could be activated by the very low concentrations of transmitter released during spontaneous quantal discharge⁶.

Enzyme activity was proportional to incubation time for both guanylate cyclase (Fig. 3) and adenylate cyclase (data not shown) for glutamate concentrations between 10⁻¹¹ M and 10⁻⁵ M, both in the presence and absence of added calcium.

As the present results represent the first evidence of the activation of guanylate cyclase by any neurotransmitter in a

broken cell preparation, the production of cyclic GMP from GTP following glutamate treatment was verified using an alternative assay procedure in which $[\alpha^{-32}P]$ GTP was used as the substrate. Essentially similar results were obtained (Fig. 4).

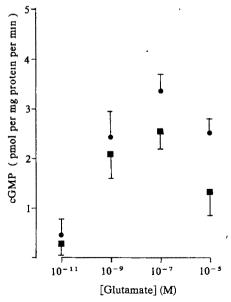

Fig. 2 Increase in guanylate cyclase activity after L-glutamate stimulation in the presence and absence of calcium Membrane preparations were isolated, incubated and cyclic GMP extracted as described in Fig. 1 legend

•, EGTA (1 mM), •, ca²⁺ (1 mM).

HPLC followed by TLC of control and phosphodiesterasetreated cyclic GMP' column eluate fractions, confirmed that the radioactive product was 3', 5'-cyclic GMP. Glutamate stimulation of adenylate and guanylate cyclase activities has also been observed for an isolated membrane preparation prepared from the body-wall muscles of a second species of dipteran insect, Lucilia sericata (data not shown).

We have made a preliminary investigation of the pharmacological specificity of adenylate and guanylate cyclase. The neutral amino acid alanine was found to be totally inactive in stimulating either adenylate or guanylate cyclase activities. However, inclusion of alanine in the incubation medium reduced considerably the level of nonspecific interference in the cyclic GMP radioimmunoassay, therefore alanine was included at a low concentration in the assay buffer, α -Ketoglutaric acid, a precursor of L-glutamate, was also found to have no stimulatory effect. The structurally related amino acids aspartate and cysteine sulphinate were also tested and found to possess agonist activity but of a lower potency than glutamate. We also determined the cation requirements necessary for measurable cyclase activity. Although Ca2+ is not required in the final incubation medium, it must be included in the isolation buffer. Preliminary studies suggest that either Mg²⁺ or Mn²⁺ may serve as the major cation in the cyclase assay buffer.

Although various authors^{7,8} have reported stimulation of guanylate cyclase activity by calcium in broken cell preparations, and Kakiuchi and co-workers9 have shown that in Tetrahymena pyriformis calcium activation of membrane-bound guanylate cyclase is calmodulin dependent, the present report of glutamate activation of guanylate cyclase in a broken cell preparation is in sharp contrast to the failure in both our own and various other laboratories to demonstrate activation by neurotransmitters of guanylate cyclase in cell-free preparations. Our present results agree with previous observations in that guanylate cyclase can be activated by calcium, but differ from previous reports in that we have demonstrated an additional glutamatesensitive component which may be activated by this neurotransmitter in the absence of calcium. It is not clear whether the neurotransmitter-sensitive guanylate cyclase reported here is unique to insect muscle or whether it represents a more general

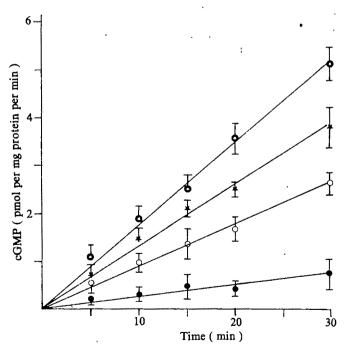

Fig. 3 Time of production of cyclic GMP by an isolated muscle membrane preparation in the presence and absence of added glutamate. Membrane preparations were isolated, incubated and cyclic GMP extracted as described in Fig. 1 legend, except for the variation in incubation time. ●, EGTA (1 mM); ○, EGTA (1 mM)+glutamate (10⁻⁷ M); ★, Ca²⁺ (1 mM), ☆, Ca²⁺ (1 mM)+glutamate (10⁻⁷ M).

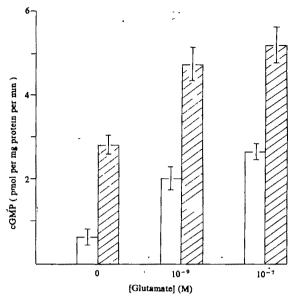

Fig. 4 Production of $[\alpha^{-32}P]$ cyclic GMP from $[\alpha^{-32}P]$ GTP. Membrane preparations were isolated and incubated as described in Fig. 1 legend except that $[\alpha^{-32}P]$ GTP (0.05 mol per mCl) was used as the substrate for the guanylate cyclese and the cyclic GMP produced during incubation was accordingly labelled with ³²P Incubations were terminated as described in Fig. 1 legend and after evaporation to dryness, samples were extracted with 1 ml extraction buffer containing 1 nmol cyclic GMP to act as a marker during HPLC. A 0.5-ml sample was introduced to the chromatography column (Whatman SAX; 10×30 cm) and the chromatograph developed by isocratic elution using 0 005 M NaH₂PO₄ buffer, pH 4 2. The column cluate was continuously minitored for UV absorbance at 254 nm and 500-µl samples collected using a Gilson fraction collector and monitored for radioactivity. The 'cyclic GMP' peak as determined by the UV absorbance of the added standard was found to correspond to a peak of radioactivity and the yield of $[\alpha^{-32}P]$ cyclic GMP calculated by determining radioactivity recovered from the column after injection of radioactive standards. Representative samples of 'cGMP' column fractions were pooled and evaporated to dryness under N₂ at 55 °C. Samples were then taken up in a small volume (20 μ l) of distilled water; 5 μ l was applied directly to TLC plates (silica gel GF, 250 μ m, with fluorescent marker) and the remainder incubated for 30 min with a high concentration of 3'5'-cyclic nucleotide phosphodiesterase (Sigma) This incubation was stopped by adding 5 vol of acidified ethanol. Samples were again evaporated to dryness under nitrogen at 55 °C and then taken up in 15 µl distilled water; a 5-µl sample was applied to a TLC plate together with the untreated sample and suitable cyclic GMP and GMP standards. The chromatogram was developed in n-butanol/ethyl/acetate/methanol ammonia/water (5:3.6.4:2). The developed chromatogram was monitored for UV absorbing spots and then 1-cm strips were scraped off and the radioactivity counted in a liquid scintillation counter This procedure confirmed that the radioactive product co-chromatographed with cyclic GMP after phosphodiesterase treatment co-chromatographed with GMP. Open columns, with added EGTA, cross-hatched columns, with added Ca2+.

system present in other tissues for which appropriate assay conditions have not yet been found.

Single Ca²⁺-activated nonselective cation channels in neuroblastoma Gary Yellen

Department of Physiology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA

Recent work suggests an important role for intracellular agents in controlling ion channels in the membranes of nerve cells and other excitable tissues. Calcium ions^{1,2}, cyclic nucleotides³ and protein kinases4,5 can all act on the inner surface of the membrane to influence ion channel activity. Earlier studies of these effects on intact cells could not, however, effectively control or measure conditions on the inner membrane surface. The technique of recording from detached membrane patches^{6,7} permits free access to the intracellular face of ion channels and makes it possible to study them in isolation from the many components of the cytoplasm. With this technique, I have studied the response of membrane patches from neuroblastoma cells to intracellular Ca2+ ions, and have found a class of nonselective cation channels activated by micromolar concentrations of Ca2+ on the intracellular face of the membrane. These channels are almost equally permeable to Na⁺, K⁺, Li⁺ and Cs⁺ ions, but are practically impermeable to Ca²⁺ ions. Similar channels were first found recently in cultured heart cells, where they probably account for the previously reported 'transient inward' current⁵. Their discovery in neuronal cells as well as heart cells suggests that this hitherto scarcely recognized channel species may be more widely distributed than previously supposed.

Voltage-clamp recordings were from inside-out^{6,7} and outside-out membrane patches of mouse neuroblastoma cells (N1E-115). Inside-out patches have their intracellular face exposed to the bath, while outside-out patches have their extracellular face exposed to the bath. The exposed surface can be readily superfused. Cells were subcultured onto glass coverslips 2-7 days before use; some cells were treated with prostaglandin E₁ (PGE₁) (10 µM; P-L Biochemicals) 2 days after subculture (L.-Y.M. Huang, personal communication). Voltage-activated Na⁺ channels were observed in most patches. Normal behaviour of Na+ channels served to indicate that patches were not sealed over; rounded channel currents usually indicate that the membrane has sealed over to form a closed vesicle7. Other channels observed were Ca2+-activated K+selective channels and various voltage-sensitive outward current channels. The Ca²⁺-activated nonselective channels were observed in about 1 out of 20 patches from cells not treated with PGE₁, and about 1 out of 5 patches from treated cells.

Channel opening and closing events like those in Fig. 1 were seen in inside-out or outside-out patches when the intracellular face was bathed in 1-50 μ M Ca²⁺. These currents had a reversal potential close to 0 mV in a variety of ionic conditions (see below), and a conductance of 22 ± 1.5 pS (s.e.m., n=6) at 24 °C, with 125 mM NaCl outside and 125 mM KCl inside.

Channel opening events occur in clusters, and their kinetics indicate a complex scheme for channel gating. A cluster of channel openings and closings may last on the order of 30 s. Within such a cluster, there are opening events lasting on the order of 50-200 ms. One of these opening events may be interrupted by brief closing events (see, for example, the -70 mV trace in Fig. 1). Clusters of openings are sometimes separated by prolonged closings of many minutes. This

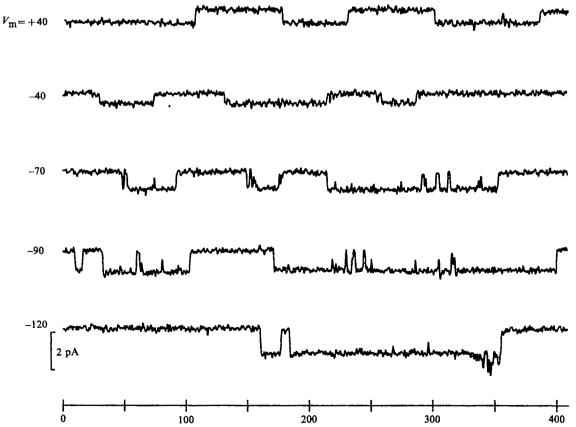

Fig. 1 Ca²⁺-activated nonselective cation channel currents. Outward current is always defined as current from the intracellular to the extracellular side of the membrane, and is indicated as upwards. Membrane potentials are always specified as the potential on the intracellular side of the membrane, relative to the extracellular side. Channel currents are outward in the +40 mV trace, and inward in all the traces at negative membrane potentials. Records are from an outside-out patch. Extracellular (bath; in mM). 125 LiCl, 2 CaCl₂, 1 MgCl₂, 10 HEPES, 70 dextrose, pH 7.2. Intracellular (pipette). 125 NaCl, 1 MgCl₂, 10 HEPES, 70 dextrose, 5 EGTA+4.925 CaCl₂ (free [Ca²⁺]=10 μM), pH 7.2. All Ca²⁺-EGTA buffers were computed with a K_{app} (at pH 7.2) = 1.48×10⁻⁷ M (ref. 13, corrected for hydrogen ion activity). Temperature 22 °C. Low-pass filtered at 500 Hz with an 8-pole Bessel characteristic.

0028-0836/82/120357--03\$01 00 © 1982 Macmilian Journals Ltd

behaviour indicates gating which is more complex than a single first-order transition between an open and a closed state. Gating of the channels is not strongly voltage dependent over a range from -120 to +80 mV.

Intracellular Ca^{2+} concentrations of $\geqslant 1 \mu M$ reversibly activate these channels (Fig. 2a), as can be seen by changing $[Ca^{2+}]$ on the exposed (intracellular) surface of an inside-out patch. If Ca^{2+} is removed (solution changed to 5 mM EGTA, 0 Ca^{2+} , 1 mM Mg^{2+}), the channel openings become less frequent and eventually cease (complete disappearance sometimes takes 1–2 min). When intracellular Ca^{2+} is restored, the channels begin to open almost immediately. This whole process can be repeated several times on a single patch, using the perfusion system shown in Fig. 2b. Solutions can be changed rapidly by moving the patch pipette among several continuously flowing perfusion streams.

The channel permeation selectivity was studied in outside-out patches, with 10 or 50 µM free [Ca2+] on the intracellular side (that is, in the pipette) to activate the channels. Two results argue against a significant anion permeability of the channels. First, replacing all but 3 mM of Cl by aspartate on one or both sides of the membrane changed neither the reversal potential nor the unit conductance. Aspartate is a much larger anion than chloride, and might be expected not to pass through the channels as easily. Second, channel currents in the presence of a salt gradient show approximately perfect selectivity for cations. In a fivefold salt gradient (25 mM NaCl extracellular, 125 mM NaCl intracellular; osmolarity preserved with dextrose), a perfectly cation-selective channel should reverse at -41 mV, and a perfectly anion-selective channel at +41 mV (22 °C). In such conditions, I found that these currents reverse within 2 mV of -41 mV.

Several alkali metal cations and Ca^{2+} were tested for permeation through the channel. All of the alkali metals permeated nearly as well as Na^+ . To obtain a complete current-voltage (I-V) relationship over a wide range of membrane potentials, a voltage ramp was applied to the membrane. Figure 3a shows a single record of membrane current in response to such a ramp (average leak current has been subtracted). When the channel opens, the current changes abruptly from the leakage level (zero in the leak-subtracted records) to the open channel level. For as long as the channel remains open, the current follows the I-V relationship for the open channel. A complete I-V relationship for the open channel may be obtained by extracting all the open channel segments from many records and averaging

them point by point for each voltage (points from one voltage are averaged only with other points from the same voltage, see Fig. 3b). The leakage current is obtained by a similar process.

The ramp clamp method has several advantages over measuring channel currents at many fixed potentials. Channel openings are small and difficult to see at fixed potentials near their reversal potential, but can readily be seen in ramp clamp records as an inflection in the slope of the current. Also, although it is sometimes difficult to distinguish between the opening of an inward current channel and the closing of an outward current channel at a fixed potential, the open channel is unambiguously identified in a ramp clamp by the increased slope of the I-V curve. Finally, a complete, continuous I-V curve can be obtained quickly, and without holding the membrane at depolarized potentials for prolonged periods (which often causes membrane breakdown). Open channel I-V curves derived from ramp clamp data agree well with those derived from measurements of fixed-potential records. Ascending and descending ramps give similar results.

The open channel I-V curve in symmetrical 125 mM Na⁺ has a slope conductance at 0 mV of ~ 17 pS (22 °C), and shows a small outward rectification at positive potentials (Fig. 3b). K⁺ goes through the channel just as easily as Na⁺: the reversal potential with Na⁺ outside and K⁺ inside is still 0 mV. Cs⁺ and Li⁺ show only slightly lower permeability than Na⁺ and K⁺, with a reversal potential of -8 mV (Cs⁺ or Li⁺ outside, Na⁺ inside) and a slope conductance at hyperpolarized voltages of ~ 12 pS. Ca²⁺ (82 mM, outside; Na⁺ inside) has a very low permeability (if any); the channel current remains outward over a range of hyperpolarized voltages (Fig. 3b).

Neuroblastoma cells have at least one other type of Ca²⁺-activated channel, a Ca²⁺-activated K⁺ channel (unpublished observations). This channel is similar in its properties to the Ca²⁺-activated K⁺ channels described by Marty¹⁰ in chromaffin cells and by Pallotta, Magleby and Barrett¹¹ in cultured rat muscle cells. Even though the Ca²⁺-activated K⁺ channels have about 10 times the conductance of the Ca²⁺-activated nonselective channels, they are much more selective in their permeation.

Recently, it was reported that pressure-injection of CaCl₂ in snail neurones evokes an inward current¹². However, this Ca²⁺-activated inward current is not affected by replacing all the extracellular NaCl with sucrose, and may thus have a different ionic basis from the Ca²⁺-activated nonselective cation channel currents described here.

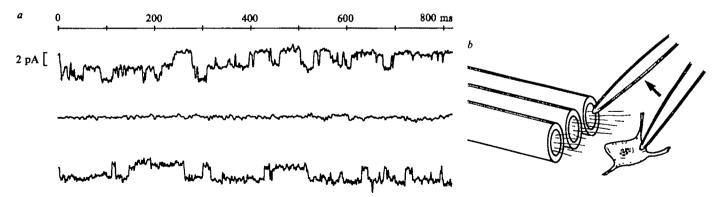

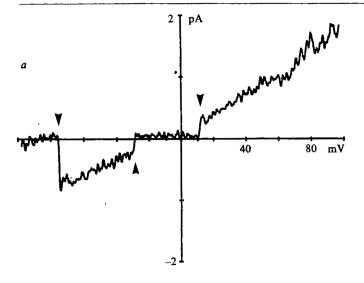

Fig. 2 a, Ca²⁺-dependent activation of channel currents. A series of records was collected with different intracellular [Ca²⁺]. Top trace: channel currents with 1 μM free [Ca²⁺] solution perfusing the intracellular side. Middle trace: current record after 2 min perfusion with 0 free [Ca²⁺] solution (that is, 5 mM EGTA, no added Ca²⁺). Bottom trace: channel currents immediately after return to 1 μM free [Ca²⁺]. Solution changes were performed using a perfusion system like that shown in b. Temperature 25 °C; 300 Hz filtering. Data are from an inside-out patch with Na⁺ saline outside (divalent ions: 3 mM MgCl₂, 0.1 μM free [Ca²⁺] (5 mM EGTA buffer)) and K⁺ saline inside (divalent ions: 1 mM MgCl₂, 1 μM free [Ca²⁺] or 0 free [Ca²⁺] (5 mM EGTA buffer)). Membrane potential is -60 mV. b, Diagram of perfusion apparatus for rapid solution changes. Solutions flow continuously out of perfusion pipettes (i.d. -70 μm) into the bath at a rate of 5-50 linear μm s⁻¹ (estimated from the velocity of small particles in the centre of the flow stream). After detaching the membrane patch from the cell, the patch pipette is moved completely into the outflow of one of the perfusion pipettes. Solution changes can be readily performed by moving the patch pipette into a different perfusion stream. Moving the pipette takes about 1 s; the solution change at the membrane is quite rapid, as judged from the immediate response of Ca²⁺-activated K⁺ channels to perfusion of Ca²⁺ solutions. This apparatus was used for changing internal [Ca²⁺] in experiments with inside-out patches.

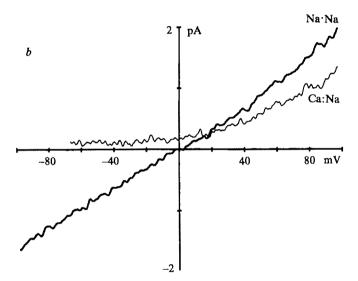

Fig. 3 Open channel I-V relationship obtained with ramp voltage clamp. a, Single current record from outside-out patch with Li⁺ saline outside, Na⁺ saline (with 10 μM free [Ca² The average leak current from 32 records has been subtracted (averaging method is described in the text). The arrows indicate channel transitions: the first arrow indicates a channel opening, the second a closing, and the third an opening. The residual current when the channel is closed is due to imperfect leak subtraction. A ramp from -100 to +100 mV was performed in 410 ms. Temperature 22 °C; 300 Hz filtering. b, Average open channel I-V curves. Open channel segments of records like that in a were identified to the computer, which averaged these segments point by point for each voltage. An average leakage I-V was subtracted from the open channel I-V (the leakage I-V was also collected by selective averaging, and, in this experiment, the leakage current was smaller than a single open channel current). The Ca:Na I-V was obtained with (in mM): 82 CaCl₂, 10 HEPES, 70 dextrose, pH 7.2 extracellular, and Na⁺ saline (10 μ M free [Ca²⁺]) intracellular. Temperature 22 °C. In measurements of the Ca:Na I-V, channel opening events were observed at potentials as low as -10 mV (size was +0.2 pA); below this potential, the currents were obtained from the average of several records which appeared to have a channel open during the whole trace.

Channels very similar to those described here have recently been found in primary-cultured rat heart cells8. They are activated by intracellular Ca²⁺, not much affected by voltage, have a size of ~23 pS at 22 °C and pass Na⁺ and K⁺ equally well. They may be responsible for the 'transient inward' current which produces oscillatory depolarizations (causing arrhythmias) in heart cells exposed to high Ca²⁺ or to Na⁺-K⁺-pump inhibitors9. The finding that these channels, appreciated only

for their role in the physiological dysfunction of cardiac cells. also appear in neuronal cells suggests that this channel species may be more widespread in both its occurrence and significance.

I thank Dr D. P. Corey for advice and encouragement, and Dr C. F. Stevens for both moral and financial support. This work was supported by NIH grant NS 12961. G.Y. is a NSF Predoctoral Fellow.

Human tumour antigens defined by cytotoxicity and proliferative responses of cultured lymphoid cells

Brent M. Vose* & Guy D. Bonnard

Laboratory of Immunodiagnosis, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

The long-term goal of many laboratories has been to develop cellular reagents having specific reactivity against human tumour cells. Such immune cells should prove useful for defining the antigenicity of human malignancies and may have important therapeutic potential, as has been clearly shown in some animal models¹. Here we describe methods of initiating continued lymphocyte cultures (CLC) having specific anti-tumour reactivity using conditioned media containing interleukin-2 (IL-2).

Direct cytotoxicity assays show that ~30% of patients have specific reactivity against autologous tumours²⁻⁴. It was anticipated that such in vivo sensitized cells would express receptors for IL-2 and thereby be selectively susceptible to growth in vitro in the presence of IL-2 (ref. 5). Blood lymphocytes were prepared from heparinized blood samples taken from cancer patients on the morning of surgery, before the administration of any narcotic agent. Mononuclear cells were isolated by flotation on Ficoll-Hypaque (Lymphocyte Separation Medium, Litton Bionetics, Maryland). Adherent cells were removed by culture in flasks (75 cm²) at 37 °C overnight. The lymphocytes (3×10⁵ ml⁻¹ in RPMI+20% heat-inactivated pooled normal human serum) were grown (without in vitro stimulation with tumour cells) in optimal quantities of different conditioned media containing IL-2 reactivity. The resulting cultured cells were tested for cytotoxicity against a range of target cells, including freshly isolated autologous and allogeneic tumour cells. CLC were also tested against the K562 cell line to determine the possible presence of natural killer (NK) cells. The cultured cells showed cytotoxicity against both autologous and allogeneic tumour targets and, in at least some conditioned media, high levels of cytotoxicity were also found against K562 (Table 1). There was no evidence of selective reactivity against the autologous tumour alone and frequently, cytotoxicity against allogeneic tumours of unrelated types exceeded that against autologous tumours. Similar data have been obtained by other workers⁶⁻⁹. The results are compatible with the presence within such cultures of several different types of effector, including polyclonally activated T¹⁰⁻¹² and natural killer (NK) cells 10,13

H-CM, from thoracic duct lymphocytes (phytohaemagglutinin (PHA) content .04 µg ml⁻¹ by haemagglutination); S-CM, from spleen lymphocytes (PHA 0.04 µg ml-1 content 2 µg ml 1), LF-CM, from tonsillar lymphocytes depleted of PHA by passage through an immunoabsorbent column of rabbit anti-PHA (no PHA detectable). Tumour tissue was received within 3 h of removal from patients Tumour cells, tumour-infiltrating lymphocytes and macrophages were isolated from enzymatically dispersed cell suspensions by methods described in detail elsewhere²¹. All populations showed high viability (>95% by Trypan blue exclusion) and contamination with 'inappropriate' cells was <10% as judged by morphological examination and histochemical staining1,20. Preparations were either used unmediately as stimulators in MLTC, or frozen in RPMI 1640 supplemented with 20% human serum and 10% dimethyl sulphoxide (2.5×106 cells in 2 ml) by constant-rate freezing at 1 °C min⁻¹ to -30 °C and stored over liquid nitrogen. Allogeneic tumours were, as far as possible, matched for cytotoxicity testing with the autologous tumours with regard to tumour site and histology. Cytotoxicity at effector/target ratio of 5 · 1 was determined after overnight incubation in fresh medium¹³, for each case.

*P<0.05, Mann-Whitney U-test.

In an attempt to induce more specific reactivity, blood lymphocytes were sensitized in vitro in mixed lymphocyte-tumour cultures (MLTC). Responder cells (1×10⁷ in 10 ml RPMI plus 20% human serum) were mixed with irradiated (3,000 R) tumour stimulators (2×106 in 2 ml medium) and cultured at 37 °C for 6 days in 25 cm² culture flasks kept upright. MLTC was considered positive when mean 3H-thymidine incorporation of stimulated cultures exceeded by at least threefold that of controls and clear dose-dependence of stimulation was apparent, and when blast cells were recognizable in bulk cultures. The factors critical for induction of high frequency of stimulation by autologous tumour cells have been considered elsewhere¹⁴. In the present experiments, positive MLTC was defined in 15 of 22 cases. Surviving lymphocytes were expanded by adding IL-2-containing media as described above, and these (MLTC-CLC) were tested for cytotoxicity after 10 and 21 days in culture. Typical results for such cultures are shown in Fig. While some preferential reactivity towards autologous

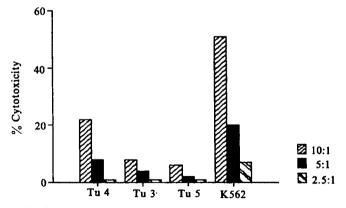

Fig. 1 Cytotoxicity of MLTC-positive cells grown in H-CM containing IL-2 for 17 days. Effectors were cultured in the absence of IL-2 for 24 h before testing and tested in a single assay at effector/target ratios of 10:1, 5:1 and 2.5:1 against the autologous tumour Tu 4 (parotid), and allogeneic tumours Tu 3 and 5 (ovarian ascites). The K562 cell line was used in measures of NK activity; cytotoxicity against the latter represented the major cytolytic potential in most of these cultures. Spontaneous ⁵¹Crrelease was: Tu 4, 21%; Tu 3, 11%; Tu 5, 14%; and K562, 7%.

tumours was induced in MLTC-positive cultures, CLC still had significant reactivity against allogeneic tumours and high cytotoxicity against K562. Thus, they were not appreciably more selective in their reactivity than unstimulated CLC.

To select for specific anti-tumour reactivity, blasts were isolated from MLTC on day 6 of culture on discontinuous gradients of Percoll in RPMI plus 20% human serum. Gradients were prepared in 15-ml tubes (No. 2095, Falcon Plastics, Maryland) and comprised 40% Percoll (5 ml); 35% (1.5 ml); 31.5% (2.5 ml) and 26% (2.5 ml). Samples were applied to the gradient in 1 ml medium and centrifuged at 550g for 30 min at room temperature. Blast cells were recovered from the 31.5% interface, lower numbers (contaminated with small lymphocytes) also being found at the 35% interface. Cells were washed twice in RPMI 1640 and cultures initiated at a concentration of 3×10^5 cells ml⁻¹ in RPMI plus 20% human serum supplemented with 10% conditioned medium containing IL-2 activity. These MLTC-blast-CLC were tested for cytotoxicity (4 h ⁵¹Cr-release assay) and proliferation after 8-29 days of culture in conditioned medium. Of 15 MLTC-blast-CLC, 13 showed selective lysis of autologous tumours (Table 2). Reactivity was apparent at low effector/target ratio and was dose dependent. By contrast, significant reactivity was only rarely recorded against at least two allogeneic tumour targets (Table 2). In many cases, cross-reactivity tests showed that the control targets were susceptible to lysis by appropriate autologous MLTC-blast-CLC. Following blast isolation, many cultures

Table 2 Cytotoxic reactivity of MLTC-blast-CLC grown in H-CM

		% Cytotoxicity (effector/target ratio, 5.1) against:		
Tumour no.	Diagnosis	Autologous tumour	Allogenesc tumour (no.)	K562
7	Lung cancer	28 4*	2.0(11)	10.1*
8	Cancer of gingiva	100*	5.7 (7)	19*
11	Lung cancer	23.7*	4.5 (7)	0
12	Melanoma	18 4*	1.4 (11)	7
15	Lung cancer	38.5*	1.4 (17)	1
17	Lung cancer	42.4*	0.4 (15)	2.7

26	Breast cancer	15.5*	2.2 (25)	16.3*

Spontaneous release of 31 Cr from fresh tumour cells was <25% in a 4 h assay; K562 showed spontaneous release between 11% and 21% of total. Tests were performed on the same day against autologous tumour, blood monocytes and PHA-induced lymphoblasts and against at least two allogeneic tumour preparations matched, as far as possible, for tumour site and histology. No significant cytotoxicity was found against six autologous lymphoblasts (cytotoxicity -5.1 to 4.7%), but was evident against 1/7 blood monocytes (tumour 12, 11.4%) and in 4/41 cross-reactivity tests with 15 MLTC-blast-CLC against allogeneic tumour (-4.3% to 18.6% cytotoxicity). *P<0.05.

showed only low levels of cytotoxicity against the K562 cell line. The ability to reduce NK-like activity by density separation facilitated the interpretation of MLTC-blast-CLC killer function against autologous tumour. However, as an additional control, CLC were initiated from blasts induced by co-cultivation of tumour cells with allogeneic lymphocytes in seven cases. Five allogeneic MLTC-blast-CLC showed significant proliferation and cytotoxicity that was specific for the inducing tumours and levels of lysis were similar to those of autologous MLTC-blast-CLC against the same targets. Some cultures (7, 8, 25 and 26 of Table 2) continued to show significant NK activity against K562. The reason for the variability of NK levels among different CLC is not clear but cannot be related to levels of proliferation of particular MLTC.

Proliferative responses of MLTC-blast-CLC were assessed in primed lymphocyte tests. Cultures were restimulated with autologous and allogeneic cells in 48-h tests; 15 MLTC-blast-CLC showed a significant increase in ³H-thymidine uptake on restimulation with autologous tumour cells. The results of a series of assays are given in Table 3. MLTC-blast-CLC from a patient with squamous cell carcinoma (SCC) of the lung showed significant proliferation after restimulation with

Table 3 Primed lymphocyte test of MLTC-blast-CLC 17 (squamous cell

Restimulation of MLTC-blast-CLC 17 with autologous (tumour, monocytes and macrophages 17) and allogeneic cells. Decreasing numbers of responder cells were cultured for 48 h with a constant number $(5\times10^4 \text{ per well})$ of stimulator cells. Uptake of ³H-thymidine was measured after a 6-h pulse with 0.5 μ Ci radiolabel per well. Uptake of ³H-thymidine by stimulators was <100 counts per well and this value was subtracted from stimulated cultures. Stimulators tested were autologous tumours (squamous cell carcinoma of lung), autologous tumourderived macrophages, autologous blood monocytes, allogeneic squamous cell carcinoma of lung, and lymphocytes from allogenesc tumour donors 16 (ref. 15). Further testing of the MLTC-blast-CLC 17 line showed that it was stimulated neither by four allogeneic lymphocytes nor by eight allogeneic non-SCC tumours. * P < 0.05, Student's t-test.

autologous tumour. Less proliferation was apparent with tumour macrophages as stimulators and no increased 3Hthymidine incorporation was induced by autologous blood monocytes, lymphocytes or a panel of allogeneic lymphocytes and monocytes. We expected that primed lymphocyte test responses might be restricted by histocompatibility at the Ia region. This restriction has affected proliferative responses to soluble antigens in mouse^{15,16} and man¹⁷. In our study, proliferative responses to malignant cells in MLTC-blast-CLC appeared to be limited by tumour site and histology, not by HLA. Three squamous cell carcinomas of the lung (one of which is given in Table 2) showed complete cross-reactivity in that allogeneic SCC also induced significant restimulation while no stimulation was induced by small cell carcinoma or adenocarcinoma of the lung, tumours of the ovary or colon, or blasts from acute myelogenous leukaemia. Similar results were obtained for CLC from nine patients with adenocarcinoma of the breast. Allogeneic tumours induced variable degrees of restimulation but levels of 3H-thymidine incorporation were often comparable with those induced by autologous tumour. The panel of stimulator cells is now being expanded to investigate further the specificity of this primed lymphocyte test response, but the data contrast with the high individual specificity seen in cytotoxicity assays. These results may be explained by HLA restriction of killing to HLA-A, -B or -C (ref. 18) or by individual tumour-associated antigens, whether or not they involve HLA restriction. The question remains as to whether the lymphocyte-stimulating and cytotoxic T-cell target antigens are different18.

We have thus obtained cultured cells having specific antitumour reactivity by adopting approaches which, in our laboratory and in others, have been effective in inducing cultured cells having specificity for alloantigens ¹⁸⁻²⁰. Critical features of these experiments were: (1) the use of MLTC-positive cultures (while cultures could be initiated from MLTC-negative individuals, no specific reactivity was found in these CLC); (2) isolation of blast cells-without this, the cultured cells showed features of polyclonal T-cell activation and high NK activity.

Using these MLTC-blast-CLC, we have demonstrated selective lysis of autologous tumours and restimulation in primed lymphocyte test assays. The nature of the antigens against which these responses were directed is now being investigated. Although there is no evidence that reactivity of specific CLC was directed against HLA-D/DR (failure to lyse autologous monocytes or undergo restimulation by monocytes and lymphocytes), the induction of autoreactivity to other 'normal' antigens, such as organ-specific or differentiation markers, cannot be excluded. We envisage that access to further normal

control tissues should aid the investigation of these reactions. as should the availability of T-lymphocyte clones.

We thank Sheldon Grove for supplying conditioned media under contract YOY DB 00319 with the Naval Medical Research Institute and the Uniformed Services University of Health Science, and Drs R. Zajtchuk, C. Alford, R. Fisher and R. Holt for clinical material. We also thank Dr R.B. Herberman for support and critical review of the manuscript.

Amplification and rearrangement of *onc* genes in mammalian species

Sisir K. Chattopadhyay*, Esther H. Chang*, Marilyn R. Lander*, Ronald W. Ellis†, Edward M. Scolnick† & Douglas R. Lowy*

* Dermatology Branch and † Laboratory of Tumor Virus Genetics, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Related eukaryotic species usually contain the same number of copies per cell of a given 'unique sequence' gene. In the few described exceptions, such as the preproinsulin1,2 and globin genes3-7, one or two additional copies per cell have been found in several related species, suggesting that germ-line amplification occurred millions of years ago in a common progenitor of these species. The transforming (onc) genes of retroviruses are a group of evolutionarily conserved genes for which at least 10 distinct members have been described (for a review see ref. 8). Sequences related to each onc have been identified in all vertebrate species tested, usually as one copy per haploid genome, although the rat has at least two different genes homologous to the onc of the rat-derived Harvey murine sarcoma virus (Ha-MuSV)9. In screening genomic DNA from several rodent species for sequences related to the onc of Ha-MuSV and to the closely related (but distinguishable) onc of Kirsten (Ki) MuSV¹⁰, we have now found evidence for relatively recent amplification of these genes. We report here that Mus pahari apparently contains at least 10 copies of Ha-MuSV-type onc, whereas most other Mus species contain only one or two copies. Similarly, Chinese hamsters (Cricetulus griseus) have about six copies of the Ki-MuSV-type onc compared with only one copy in Syrian hamsters (Mesocricetus auratus).

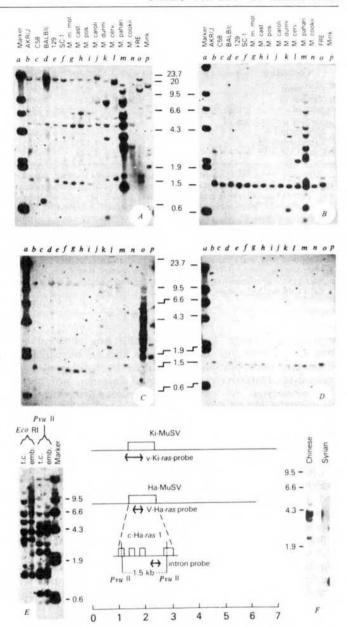

In agreement with recently proposed nomenclature¹¹, the onc of Ha-MuSV has been designated v-Ha-ras, while the two homologous rat cellular genes which have been molecularly cloned are called c-Ha-ras1 and c-Ha-ras2 respectively. (In ref. 9, c-Ha-ras1 is called sarcII and c-Ha-ras2, sarcI. Sarc II

is called c-Ha-ras 1 because it is the most highly conserved form of c-Ha-ras ¹².) Each rat cellular gene is homologous to v-Ha-ras in ~0.9 kilobase (kb)⁹. In c-Ha-ras 2 these homologous sequences are co-linear with v-Ha-ras, while c-Ha-ras 1 has intervening sequences (introns; see Fig. 1). The rat c-Ha-ras 1 gene, v-Ha-ras and v-Ki-ras (the onc of Ki-MuSV), each encode 21,000-molecular weight proteins (p21) which are biologically, immunologically and functionally related 9.10,13-15, although v-Ha-ras and v-Ki-ras DNA probes hybridize in stringent conditions to different restriction enzyme fragments of vertebrate genomic DNAs 10. High levels of virus- or cell-encoded p21s can induce cellular transformation 9.10,13.

To detect and analyse the ras sequences in rodent DNA, EcoRI-digested embryo or tissue culture genomic DNAs from several inbred strains of M. musculus, as well as from other Mus species, rat and mink (a non-rodent), were electrophoresed, transferred to nitrocellulose paper and hybridized to a probe derived from either v-Ha-ras or v-Ki-ras (Fig. 1A, C). The v-Ha-ras probe detected the same c-ras fragments in all M. musculus and in Mus castaneus and Mus poschiavinus (Fig. 1A), while the pattern of c-ras fragments was distinctive for the DNAs from mink, rat, and the other Mus species. The most striking observation, however, was that, in contrast to the relatively few c-ras fragments in the other species, the DNA of a M. pahari cell line (Fig. 1, lane m) contained many fragments which hybridized strongly to the v-Ha-ras probe. We estimate that these fragments represent at least 10 copies per haploid genome. As the v-Ki-ras probe hybridized to only two fragments in M. pahari DNA (Fig. 1C), we conclude that the amplification in M. pahari consisted of c-Ha-ras sequences. (The multiple fragments seen in rat DNA using the v-Ki-ras probe are due, as noted previously10, to the presence of some non-ras viral sequences in the probe; hybridization of cloned human c-Ki-ras DNA12 to rat DNA revealed only four EcoRI fragments; data not shown.) The amplification of the Ha-ras sequences in M. pahari was not a result of in vitro propagation of the cell line, as hybridization of genomic DNA from both the cell line and M. pahari embryos obtained from a different colony gave almost identical results (Fig. 1E). This result also suggests that the amplification is relatively stable in M. pahari. The transcriptional activity of these multiple c-Ha-ras sequences has not yet been determined, but the M. pahari cell line, which is not morphologically transformed, contains low levels of p21 comparable with those found in other normal tissue culture cells from many other vertebrate species16 (data not shown).

As the rat c-Ha-ras1 contains a 1.5 kb PvuII fragment which serves as a useful marker for the gene (see diagram in Fig. 1), PvuII-digested genomic DNAs were hybridized with the v-Haras probe and with a probe derived from an intron of rat c-Ha-ras1 located within the 1.5 kb PvuII fragment (Fig. 1B, D). For all Mus species the intron probe hybridized selectively to a 1.5 kb PvuII fragment which co-migrated with the rat c-Ha-ras1 1.5 kb PvuII fragment, whereas mink DNA did not contain this fragment (Fig. 1D). The intensity of the 1.5 kb fragment was similar in M. pahari and other cell DNAs. Hybridization of the v-Ha-ras probe to the genomic DNAs (Fig. 1B) revealed that M. pahari contained many more PvuII fragments than did the other DNAs. These results strongly suggest that the gene carrying the intervening sequences is highly conserved among the rodents and that most or all of the additional copies of c-Ha-ras in M. pahari do not contain sequences homologous to the intron probe. The data from the non-rodent (mink) DNA also suggest that the intron sequences are less highly conserved than are the exon sequences of c-Haras1.

The amplification of p21-related sequences is not limited to Ha-ras. Genomic DNA from Chinese hamster ovary (CHO) cells digested with EcoRI contained at least eight fragments which hybridized to the v-Ki-ras probe, whereas Syrian hamster DNA contained only one such fragment (Fig. 1F). Similar results have been obtained with BamHI and KpnI digestions

Blot hybridization of genomic DNAs to ras probes. Restriction endonuclease-digested high molecular weight DNAs were electrophoresed in 0.5% agarose slab gels, transferred to nitrocellulose filters²⁶ and hybridized to cloned *ras* DNA labelled with ³²P by nick-translation²⁷. A and B, P-labelled v-Ha-ras hybridized to EcoRI-digested and PvuII-digested cell DNA respectively. C, 32P-v-Ki-ras vs EcoRI-digested cell DNA; D, ³²P-intron of c-Ha-ras vs PvulI-digested cell DNA. E, ³²P-v-Ha-ras vs M. pahari tissue culture (t.c.) and embryo (emb.) DNA. F, ³²P-v-Ki-ras vs EcoRI-digested hamster cell DNA. In A-D, AKR/J, C58, BALB/c and 129 DNAs were isolated from embryos, and other DNAs were isolated from tissue culture cells. M. m. mol, Mus musculus molossinus; M. cast., M. casteneus; M. pos., M. poschiavinus; M. cerv., M. cervicolor; FRE, Fischer rat embryo cells. Marker was ³²P-labelled HindIII-digested λ DNA. Fragment sizes are in kb. The M, pahari adult tail tissue culture line²⁸ (t.c. in E) was established in 1979 from a mouse provided by T. C. Hsu; the embryo DNA (emb.) was isolated from a mouse provided in 1981 by Richard Sage. In F, Chinese = CHO cells²⁹; Syrian = Syrian baby hamster kidney cells³⁰. In A, the probe has hybridized to four fragments of M. musculus DNA: 23, 7, 5 and 1.5 kb. In other experiments the v-Ha-ras probe consistently hybridized to the 23 kb fragment, but the hybridization to the other fragments was less consistent. The 7 and 5 kb fragments probably represent uncharacterized sequences homologous to c-Ha-ras. The 1.5 kb fragment probably represents c-Ki-ras sequences, as the v-Ki-ras probe consistently hybridizes to a 1.5 kb fragment (B). In the diagram, the relative locations of the ras sequences in the linear viral DNAs are indicated by a rectangle. The locations of sequences in the rat c-Ha-ras1 gene homologous to v-Ha-ras are shown by boxes; the spaces between these boxes represent introns. The arrow beneath each DNA indicates the location of sequences in each probe: the v-Ki-ras probe is the 0.6-kb SstII/HincII fragment of clone HiHi-3 (ref. 10); the v-Ha-ras probe is clone BS-9 (ref. 9), and the intron probe is a 0.3 kb HincII fragment obtained by electroelution from a clone of c-Ha-ras1 in pBR322 (ref. 9).

(data not shown). As in the case of the M. pahari embryos, DNA from Chinese and Syrian hamster embryos resembled DNA from the cell lines of the respective species (data not shown).

Since closely related species contain only one or two copies of these amplified gene sequences, the ras copy number has probably increased relatively recently in M. pahari and in Chinese hamsters. The ras amplification therefore differs from other amplified unique sequence genes, such as globin and preproinsulin, in its high copy number and recent origin, from that of described orphons¹⁷ in its stability and in its affecting unique sequence genes, and from the transient nonchromosomal amplification of ribosomal genes during amphibian oogenesis1

The structure of the amplified ras sequences remains to be established. The lack of homology to the intron of c-Ha-ras1 indicates that the amplified Ha-ras genes differ in structure from the c-Ha-ras gene with introns. The results suggest that these sequences may represent genes which lack introns entirely, as was the case in the rat c-Ha-ras2 gene, although the data reported here are compatible with other structures. If the amplified sequences lack introns, their structure would also resemble that of c-mos, the onc which gave rise to the transforming sequences of Moloney murine sarcoma virus¹⁹, and of an α -globin pseudogene which is present in mice and other species^{3,4,7}. The analogy of c-mos suggests that, unlike pseudogenes, the amplified ras sequences might encode a biologically active p21.

It is not known what conditions and molecular mechanisms led to the amplification of the ras genes, whether the amplified genes are clustered or dispersed, or what the biological consequences of this amplification may be. Analysis of the sensitivity of the M. pahari and Chinese hamster cells to the biological activity of p21, the distribution of the ras sequences within the cell genome, the structure of the amplified genes and their biological potential should, however, yield significant insights into these amplified sequences.

The amplification is probably not due to a general tendency of these animals to amplify genes as in M. pahari neither the closely related c-Ki-ras sequences nor the β -globin sequences were amplified (A. Leder, personal communication). The amplification might represent a genetic response to a noninfectious environmental agent, such as a chemical. Marked amplification of the dihydrofolate reductase (DHFR) gene has been induced in tissue culture cells in response to methotrexate; in cells with stable methotrexate resistance, the amplified DHFR genes are chromosomal and clustered²⁰. Alternatively, because transforming retroviruses arise by transduction of cellular onc genes⁸, the amplification might have arisen by this mechanism through putative endogenous retrovirus-like sequences or even through horizontal viral infection. In this model the ras sequences would be dispersed, as the termini of retroviral genomes resemble those of transposons and they integrate at multiple sites^{21,22}. In addition, endogenous retroviral genomes are usually found in multiple copies and may be absent from closely related species²³. This mechanism may also be relevant to the mouse α -globin pseudogene which lacks introns; it is not linked to the α -globin cluster²⁴ and has recently been found to be flanked by A-particle genes25, which are retrovirus-like genetic elements. Finally, the amplification may represent a response to a functional lesion in p21 or to a relative resistance of these cells to the protein. However, we presume that the animals tolerate the amplification because these amplified genes are not ordinarily expressed, as suggested by the normal p21 levels in the M. pahari cell line, but firm conclusions must await further study of the expression and biological potential of these genes.

DNA sequence homology and chromosomal deletion at a site of SV40 DNA integration

James R. Stringer

Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, USA

The structure of simian virus 40 (SV40) DNA insertions is different from those of retrovirus proviruses and movable genetic elements. No single DNA sequence in either the cell or the SV40 genome serves as an obligatory site of SV40 integrative recombination1-9, and SV40 DNA insertions are not bordered by the repeat structures characteristic of transposons and retrovirus proviruses¹⁰⁻¹⁵. Integration of SV40 could involve the matching of short stretches of homologous sequences present in the otherwise heterologous SV40 and cellular genomes. To explore this possibility, I have now sequenced a rat DNA fragment that contains an unoccupied site of SV40 DNA integration. Comparison of this sequence with that of SV40 and that at the rat-SV40 recombinant junction allowed two conclusions: first, SV40 DNA became linked to rat DNA at a point where the two genomes shared 5 base pairs (bp) of DNA sequence homology; and second, a rearrangement of the rat genome, probably a deletion of at least 3 kilobases (kb), occurred at the site of SV40 integration.

The SVRE9 cells, chosen for this study, were Fisher rat embryo fibroblasts that were transformed by infection with SV40¹⁶. In previous work, the single viral DNA insertion in those cells was cloned and the sequences at the rat-SV40 junctions were determined8. Figure 1 shows the structures of the cloned SV40 DNA insertion, Sst9, and the subcloned SV40rat junction fragments, 9M and 9L.

To test their suitability as probes with which to isolate a rat DNA fragment containing the unoccupied site of SV40 integration, junction fragments 9M and 9L were radiolabelled and hybridized to Southern¹⁷ blots of restriction endonucleasedigested rat DNA. 9M DNA was unsuitable in that it hybridized to many size species of endo: R: EcoRI-digested rat DNA, indicating that this junction fragment contained a sequence that was repeated many times in the rat genome (not shown). By contrast, 9L DNA hybridized to a single rat DNA fragment and was apparently free of repeated DNA sequences (see Fig. 2).

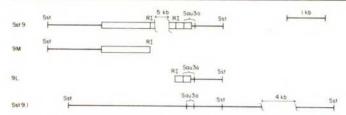

Fig. 1 Physical maps of cloned DNA fragments. Open bars represent SV40 DNA, lines represent cellular DNA. Sst9 was cloned from a λ phage library, 9M and 9L were cloned in plasmid pBR322. Cloning and analysis of this DNA were as previously described. Clone Sst9.1 was isolated as described in the text and mapped by restriction endonuclease analysis and by hybridization using 9L DNA as a probe. The DNA fragments are drawn to align homologous sequences.

Figure 2 shows that SVRE9 cells contained two DNA fragments with homology to 9L DNA; one fragment co-migrated with the fragment bearing the SV40 DNA insertion, and a second fragment co-migrated with the normal rat DNA fragment homologous to 9L DNA. These data are most simply interpreted to indicate that SVRE9 cells are haploid for their single SV40 DNA insertion; the two SVRE9 DNA fragments detected by the 9L DNA probe probably originated from a pair of homologous chromosomes, one carrying the SV40 DNA insertion and the other containing a copy of the unoccupied SV40 integration site.

The putative unoccupied integration site was isolated from a library of endo: R: SstI-digested SVRE9 DNA using procedures previously described^{8,9}. The chimaeric λ phage Sst9.1 (shown in Fig. 1) contained two SstI fragments 4 kb and 6 kb in size. Analysis by restriction endonuclease digestion and blot hybridization (Fig. 3 and other data not shown) mapped the 9L homology to one end of the 4 kb fragment of Sst9.1 DNA, as indicated in Fig. 1.

To determine whether any of the DNA sequences flanking the 9M junction were present in Sst9.1 DNA, radiolabelled 9M DNA was hybridized to Southern blots of SstI-digested Sst9.1 DNA. As shown in Fig. 3, none of the DNA in Sst9.1 was homologous to 9M DNA. The absence of homology between 9M DNA and Sst9.1 DNA is most simply explained by deletion of at least 3 kb of the rat genome at the site of SV40-rat DNA linkage in the SVRE9 progenitor cell.

Analysis of Sst9.1 DNA by restriction endonuclease digestion and blot hybridization localized the SV40 integration site to a 200-bp endo: R: Sau3a fragment (see Fig. 1). The nucleotide sequence of this DNA fragment was determined by the protocol of Maxam and Gilbert¹⁸ and the results are shown in Fig. 4. Comparison of the Sst9.1 DNA sequence with those of SV40 and the 9L junction revealed that SV40 DNA and rat DNA shared a 5-bp sequence homology at a point coincident with the rat-SV40 junction in 9L DNA.

This is the first direct demonstration that DNA sequence homology may mediate integrative recombination between SV40 DNA and the cellular chromosome. Two other studies indicate that animal cells have the ability to recombine heterologous DNA molecules through short sequence homologies. Gutai¹⁹ found two cases of 3-bp homologies at virus-virus recombinant joints in naturally arising variants of SV40. M. Botchan and co-workers (personal communication) have found evidence that short sequence homologies are involved in the imprecise excision of a SV40 DNA insertion.

The DNA sequence of the unoccupied SV40 integration site shown in Fig. 4 is striking in two ways. It is repetitive, containing 12 T \cdot G pairs in tandem, and it is composed almost entirely of G and T. Thus, this DNA chain is simple in both its sequence arrangement and its base composition. The T \cdot G repeat does not extend past the nucleotides shown in Fig. 4. In addition to the 34 bases shown, the sequence 80 nucleotides to the left and 25 nucleotides to the right were determined. The T \cdot G repeat is remarkably similar to the 'simple sequence' DNA

reported by Slightom et al.20 to be present in the second introns of human y-globin genes. Comparison of sequence similarities and differences between allelic $^{A}\gamma$ genes and non-allelic $^{G}\gamma$ and A y genes led these authors to suggest that this simple sequence region was a hot spot for DNA exchanges leading to gene conversion. As the non-allelic human γ -globin genes are $\sim 97\%$ homologous, simple sequence DNA is postulated to provide more than sequence homologies through which to initiate strand exchanges between genes. Rather, simple sequence DNA seems to act specifically by virtue of its unusual sequence, at least in the case of human y-globin genes. Gene conversion has been suggested as a mechanism by which multi-gene families may conserve the identity of their members²¹, and simple sequence DNA may be of general importance in the gene conversion processes. The T · G repeat found in rat DNA may thus be one of many such repeats in the cellular genome.

These considerations bear on the evaluation of the possible contribution of the simple sequence DNA in Fig. 4 to the integration of SV40 DNA. There are two obvious possibilities: (1) simple sequence DNA may be a target for specialized recombination enzymes designed to accomplish gene conversions; these enzymes may act to integrate SV40 DNA. (2) Simple sequence DNA may be present in many copies, thereby increasing the probability of integration in such a sequence.

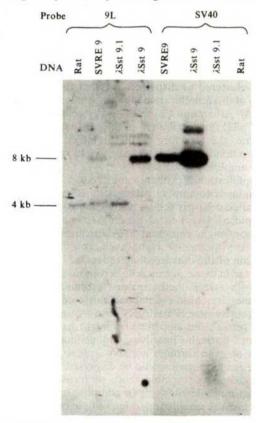

Fig. 2 Detection and sizing of rat DNA fragments containing sequences homologous either to SV40 DNA or to DNA flanking the 9L junction of the SV40 DNA integrated in SVRE9 cells. DNA (10 µg) from either Fisher rat embryo cells or SVRE9 cells were digested with SsfI and electrophoresed through 1% agarose in 36 mM Tris, 30 mM NaH2PO4, 1 mM EDTA pH 7.5. Chimaeric λ phage, Sst9 and Sst9.1, bearing the DNA fragments shown in Fig. 1, were mixed with calf thymus DNA and cut with SsI. 1×10^{-5} µg of each phage DNA was run in parallel with rat cell μg of each phage DNA was run in parallel with rat cell DNA samples. By methods previously described1, gels were blotted on to nitrocellulose which was then hybridized to either 9L DNA in pBR322 or SV40 DNA, each of which had been labelled to high specific activity by nick translation. DNA homologous to radioactive probes was detected by autoradiography. Faint bands in A Sst9 and A Sst.9.1 tracks in the 9L panel are due to weak hybridization between pBR322 and λ arms. Minor bands in λ Sst9 track in SV40 panel are partially digested chimaeric phage DNA.

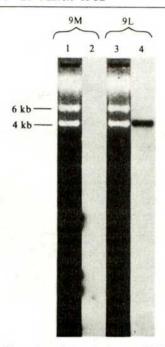

Fig. 3 Lack of homology between the rat DNA sequences in clone Sst9.1 and the rat DNA flanking the 9M junction of the SV40 DNA integrated in SVRE9 cells. A λ phage-bearing Sst9.1 DNA (Fig. 1) was digested with Ssf1 and electrophoresed on a 0.7% agarose gel. The gel was stained with ethidium bromide, photographed under UV illumination, blotted and the blot hybridized to one of two radiolabelled probes: 9M DNA, lanes 1 and 2; or 9L DNA, lanes 3 and 4. Lanes 1 and 3 are ethidium bromide-stained gels. Lanes 2 and 4 are autoradiographs of the same gels, blotted and hybridized as described elsewhere 9 M DNA did not hybridize to either of the cell DNA fragments in Sst9.1, while 9L DNA hybridized strongly to the 4-kb DNA fragment present in Sst9.1

Although both possibilities are attractive, there is no reason to believe that simple sequence DNA is necessarily involved in integration of SV40 DNA. The sequence labelled 'SVRE9' in Fig. 4 shows that homologous recombination of SV40 DNA with a portion of the repetitive rat DNA sequence generated a SV40-cell junction in which the terminal viral sequence, TGTGT, is repeated in the adjacent cellular DNA. In previous analysis of the nucleotide sequences at other cell-virus junctions, I found a similar repeated structure, composed of C and T, present at one junction of the SV40 DNA insertion present in SVRE17 cells8. However, of the six cell-virus recombinant junctions compared in that study, only two, one junction of SVRE9 and one of the SVRE17 DNA insertion, showed repeat structures. In addition, none of the three viral DNA insertions compared in that study showed repeat structures at both ends of an integrated SV40 DNA. Therefore, although it is not uncommon, repeated, simple sequence DNA is not a requisite feature of DNA adjacent to SV40 DNA insertions. The data in Fig. 4 suggest that the presence of a terminal repeat structure at a cell-virus junction may be indicative of homologous integration into a repeated cellular sequence, but the lack of such structures does not rule out homologous recombination with non-simple sequence DNA.

Integration of SV40 DNA may exploit the great sequence complexity of the mammalian genome. Any 5-bp sequence present in the SV40 genome would be expected to occur of the order of 10⁶ times in the unique sequence component of a rat cell genome. Perhaps integration is initiated when a random short sequence in the viral genome finds its match in chromosomal DNA. Integration might be completed by a second, independent ligation reaction at a different chromosomal location. Such a mechanism, of course, would generate chromosomal deletions at integration sites. Models predicting chromosomal deletions have been proposed previously (ref. 6 and

Botchan in ref. 22) and all evidence to date indicates that deletion of substantial amounts of the cellular chromosome is a consequence of SV40 DNA integration. The SVRE9 chromosome suffered a loss of at least 3 kbp of DNA, and there has been one other report consistent with chromosomal deletion at a SV40 DNA integration site. Analysis of a third SV40 DNA insertion, in SVRE17 cells, also indicates a loss of chromosomal sequences at the site of SV40 DNA integration (J.R.S., unpublished data). Three examples do not compel the conclusion that SV40 DNA integration is always accompanied by chromosomal deletions, but no exceptions have yet been found.

The finding of short sequence homology at a SV40 DNA integration site implies that DNA sequence homology might direct an exogenous DNA to integrate homologously into a unique chromosomal copy of itself. This is the case in yeast cells; exogenous yeast genes recombine homologously with their chromosomal counterparts²³. However, there is reason to doubt the ability of animal cells to match an exogenous DNA sequence efficiently with a single chromosomal copy of the same sequence. Botchan et al.²⁴ reported that when SV40-transformed rat cells were superinfected with SV40, the newly introduced viral genomes did not integrate into pre-existing SV40 DNA insertions. The difference between yeast cells and rodent cells may simply reflect the larger size of the mammalian genome. Exogenous SV40 DNA may not be able to find a single chromosomal copy of itself, and instead be integrated through the mediation of a short, but highly frequent, random sequence homology. Whatever the reason, integration of exogenous DNA into a unique homologous chromosomal site of an animal cell genome seems to be a low probability event.

SV40 integration is the best studied case of incorporation of a foreign DNA molecule into the cellular genome. Many SV40 DNA insertions have been analysed by restriction endonuclease mapping¹⁻⁷ and six SV40-cell recombinant junctions have been sequenced^{8,9}. These studies have established that, unlike retroviruses and movable genetic elements, integration of SV40 DNA insertions does not involve specific DNA sequences in either the viral or cellular genomes, nor does it involve generation of short duplications of host sequence at the point of integration. Although analysis of more unoccupied sites of SV40 DNA insertion will be needed to understand fully the role of base pairing in SV40 integration, the data presented above demonstrate that cells are able to use a short sequence homology to integrate an otherwise heterologous SV40 DNA molecule. This example of homologous recombination suggests an additional difference between integration of SV40 DNA and retroviruses and transposition of movable elements.

Understanding cellular recombination systems that foster integration of exogenous DNA is important in assessing the practicability of schemes that propose the introduction of therapeutic genetic material into the genomes of defective cells. Integration of SV40 DNA probably reflects the action of a cellular recombination system that can incorporate any foreign

Fig. 4 DNA sequences at the SV40 integration site. The sequence in Sst9.1 DNA homologous to the rat DNA immediately adjacent to SV40 DNA in clone 9L was shown, by hybridization experiments, to lie in a 200-bp Sau3a fragment (see Fig. 1). The nucleotide sequence of 140 bp of this DNA was determined by the method of Maxam and Gilbert 18, and the relevant portion of the sequence is labelled 'Rat'. Also shown is the sequence of SV40 DNA as reported by Reddy et al. 25, and the sequence at the 9L junction of the SV40 DNA insertion in SVRE9 cells, as previously determined by J.R.S. Vertical lines designate homologous nucleotides. Comparison shows that SV40 DNA and rat DNA share 5 bp of homology at a point coincident with the SV40-rat junction in the cloned 9L junction fragment.

DNA into the cellular genome, and analysis of SV40 DNA insertions may predict the fate of other exogenous DNAs. Although cells may incorporate exogenous DNA efficiently, that DNA is unlikely to integrate into a homologous single-copy sequence in chromosomal DNA. Instead, foreign DNA might be expected to integrate randomly through a mechanism that uses short sequence homologies, and generates chromosomal deletions

I thank Laurel Garbarini for technical assistance, Patti Barkley, Mike Ockler and Eric Lockhart for help in preparing the manuscript, Joe Sambrook for suggesting improvements in the manuscript and Mike Botchan for drawing my attention to the potential significance of simple sequence DNA. This work was supported by PHS CA-13106 and NCI grant CA-06460.

Influenza virus RNA is synthesized at fixed sites in the nucleus

D. A. Jackson, A. J. Caton, S. J. McCready* & P. R. Cook

We have recently shown that cellular RNA is synthesized at a sub-nuclear structure, the nuclear cage1, which contains proteins also found in other structures called variously the nuclear pore complex, lamina, envelope and matrix²⁻⁶. Is the RNA of an exogenous virus also synthesized at the cage? We chose to study influenza virus as it is unusual in its requirement for a host cell nucleus even though there are no cellular counterparts to the transcription of the infecting negative strands of genomic influenza RNA, nor to the replication of the resulting positive RNA strands to form new virion RNA. The cellular sites of these processes have not yet been definitively demonstrated⁷ We now show that nascent viral transcripts are closely associated with the cage and we conclude not only that transcription and replication of viral RNA are nuclear, but also that they occur at fixed sites in the nucleus.

Several observations suggest a nuclear involvement during the transcription and replication of influenza virus⁷⁻¹⁰. These include nuclear labelling in autoradiographs, inhibition of viral production by actinomycin D and α -amanitin—both inhibitors of nuclear RNA polymerase II—and the splicing and methylation of viral mRNA. However, attempts to demonstrate directly the site of viral RNA synthesis by pulse-labelling and cell fractionation have yielded variable results 11-13. We believe that this variability is caused by long pulse-labels (≥30 min) and nucleolytic action during cell fractionation, both of which permit

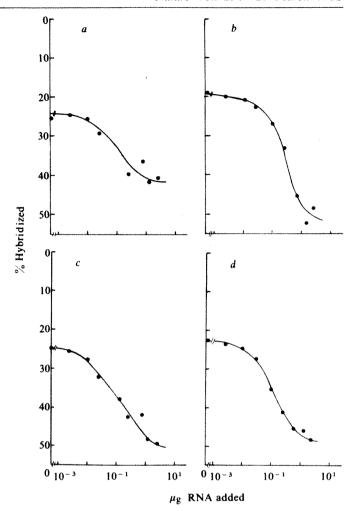

Fig. 1 The proportion of viral transcripts in pulse-labelled RNA from infected cells. Cells were infected and pulse-labelled (2.5 min) with 3 H-uridine after 2.5 h (a, b) or 4.5 h (c, d). Nucleoids were then isolated as described in Table 1 legend, pulse-labelled RNA was purified and hybridized with various amounts of virus-specific RNA obtained from purified virions (vRNA) or by extracting polyadenylated RNA from the cytoplasm of infected cells 7 h post-infection (mRNA)¹⁸. (Such a mRNA preparation is impure and contains some cellular RNA, and perhaps low levels of vRNA. However, the cellular impurities have no complements and so cannot form hybrids.) Less than 5% of pulse-labelled RNA from uninfected cells hybridized with these virus-specific RNAs. The per cent forming a hybrid resistant to S_1 nuclease was determined S_1 . Hybridizations (10 days) were carried out in a volume of 5 µl containing at least 5,000 c.p.m. of pulse-labelled RNA (~2.5 μg of total nucleoid RNA), 2.5 μg tRNA and up to 2.5 μ g mRNA (a, c) or vRNA (b, d). These conditions give a maximum C_0t of 10^3 mol s l

transfer between cell compartments. We have therefore used very short pulses (2.5 min) and a cell fractionation procedure which minimizes nucleolytic degradation.

Embryonic chick fibroblasts were lysed in a non-ionic detergent, 2 M salt and a chelating agent. The resulting nucleoids were sedimented free of cytoplasmic material and contained naked histone-free DNA packaged within a flexible cage of RNA and protein¹⁴⁻¹⁷. Their DNA, which is looped by attachment to the cage, is supercoiled^{14,15}, indicating that nucleolytic degradation has been suppressed during isolation.

When mock-infected fibroblasts are incubated with ³Huridine for 2.5 min, 96% of the cellular radioactivity which is insoluble in trichloroacetic acid subsequently co-sediments with nucleoids (Table 1). Nearly all the label also co-sediments with nucleoids made from infected fibroblasts pulsed at early (2.5 h) or late (4.5 h) times during infection. We determined what proportion of nascent RNA in infected cells was virally coded

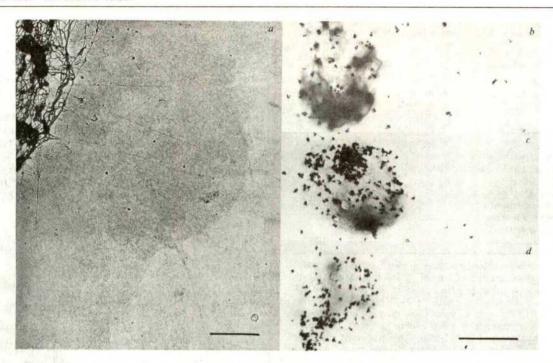

Fig. 2 Electron micrographs of nucleoids spread by Kleinschmidt's procedure. a, A typical spread illustrating part of the cage and skirt of tangled DNA fibres, which extend to the edge of the field. b-d, Autoradiographs of spreads 19 after labelling uninfected fibroblasts for b, 24 h with 3 H-thymidine $(0.01 \,\mu\text{Ci ml}^{-1}; 58 \,\text{Ci mmol}^{-1})$ or for c, 2.5 min with $[5-6-^{3}\text{H}]$ uridine and $(2,5'-8-^{3}\text{H}]$ adenosine (both at $100 \,\mu\text{Ci ml}^{-1}$ and $\sim 40 \,\text{Ci mmol}^{-1})$; or d, infected fibroblasts $4.5 \,\text{h}$ post infection for 2.5 min with ^{3}H -uridine and ^{3}H -adenosine as in c. So that silver grains can be easily counted in b-d, DNA is shadowed but not stained and can be seen spread to the edge of the field only at higher magnifications. In b, grains lie over both cage and skirt, whereas in c and d they lie predominantly over the cage. Conditions for infection are described in Table 1 legend. The bars in a and d represent 5 and 2.5 μ m respectively. b-d Are at the same magnification.

by isolating pulse-labelled nucleoid RNA and hybridizing it with an excess of unlabelled virion (v) RNA or mRNA (Fig. 1), which hybridize with strands of positive and negative polarity respectively18. In the absence of added vRNA or mRNA, <1% of the pulse-labelled RNA from mock-infected cells selfanneals, reflecting the asymmetric transcription of cellular DNA. In contrast, about 25% from infected cells self-anneals, reflecting the synthesis of both positive and negative strands. In the presence of an excess of either vRNA or mRNA, 45-50% of the pulse-labelled RNA hybridizes, whereas ~70% hybridizes in the presence of an excess of both vRNA and mRNA (results not shown). We cannot give a precise estimate of the proportion of nascent transcripts which are viral, as our mRNA probe is impure (see Fig. 1 legend) and the significance of the self-annealed values is difficult to assess. Nonetheless, it is clear that positive and negative viral transcripts constitute a significant proportion (>50%) of the pulse-labelled material.

The pulse-label might co-sediment with cages, either because it is specifically attached or because it is tangled in the high concentration of nuclear DNA. We tested the latter possibility by finding out whether RNA could be released on detaching DNA from the cages. Cells were labelled with ¹⁴C-thymidine for 24 h to label their DNA uniformly, then infected and subsequently pulsed with ³H-uridine. Nucleoids were isolated, incubated with the restriction endonuclease, *EcoRI*, the cages were filtered free of detached DNA and the amounts of the two labels remaining associated with them determined ¹⁹ (Table 1). When >75% of the ¹⁴C (that is, DNA) was detached, <1% of the ³H (RNA) was lost, showing that the pulse-labelled RNA cannot be detached with DNA from the cages.

A second experiment confirms that nascent RNA is not simply entangled in DNA or the cage. When nucleoids are spread on an air-aqueous interface, their DNA, initially confined within the cage, spreads out from the cage to form a surrounding skirt of tangled DNA fibres¹⁷ (Fig. 2a). Cages from chick fibroblasts are not as robust as those of the HeLa nucleoids that we have studied extensively, so the DNA is less protected

from shear. As a result, more is broken and therefore appears relaxed after spreading. The spread DNA is less dense, reflecting the lower DNA content of the diploid chick nucleus. The distribution of DNA in skirt and cage was obtained by reference to autoradiographs of spreads prepared from cells containing uniformly labelled DNA (Fig. 2b); 53% (average of 15 spreads) of the DNA is outside the cage. However, when cells—whether infected or not—are pulse-labelled with ³H-uridine for 2.5 min, >85% of the grains lie over the cage in each of 10 spreads selected at random (Fig. 2c, d). The proportion of grains lying over the nucleolus is reduced in spreads from infected cells (see Fig. 2c, d) late in infection, reflecting the reduced percentage of ribosomal (cellular) RNA synthesis in the total. The nascent RNA—largely viral—is unable to escape with the DNA from the cage.

A trivial explanation consistent with these results is that nascent viral RNA, synthesized throughout the nucleus, might stick nonspecifically when nucleoids are prepared. Our earlier study1 showed that nascent RNA in uninfected HeLa cells was specifically attached at the 5' end, whereas added RNA, or RNA synthesized in vitro, was either unattached or was nonspecifically associated with cages but could be detached from them by EcoRI or spreading. Using identical conditions we have shown here that nascent viral RNA is inseparable from cages. Three further controls make a nonspecific association even less likely. First, when pulse-labelled RNA from infected cells is purified and mixed with unlabelled infected cells immediately before lysis, <3% of the pure RNA co-sediments with the nucleoids, indicating that the added RNA has little affinity for cages. Second, we have confirmed earlier results9 which showed by autoradiography that all the pulse-labelled RNA in infected cells was nuclear. After a 2-h chase, the total number of grains over the cell was reduced, reflecting turnover: half lay over the nucleus, the remainder being cytoplasmic (results, not shown, of experiments using conditions described in Table 1). When these cells are lysed in 2 M salt, only 40% of the label now co-sediments with the nucleoids (Table 1). Although

Table 1 Pulse-labelled RNA is closely associated with cages

	% Label co-sedimenting with nucleoids	associa cages incul	remaining ted with after pation

Cells 2.5 h post-infection (2.5 min pulse) Cells 2.5 h post-infection	93	25	99
(2.5 min pulse, 2 h chase)	40		_
Cells 4.5 h post-infection (2.5 min pulse)	92	20	100

Primary chick embryo fibroblasts were grown³⁰ for 24 h in [Me
14C]thymidine (0.01 µCi ml⁻¹; 58 Ci mmol⁻¹), infected (MOI 100:1) where appropriate with influenza virus (influenza A/PR8/34) and 2.5 or 4.5 h later pulse-labelled with [5,6-3H]uridine (2.5 min; 100 μCi ml⁻¹; ~40 Ci mmol⁻¹). In some cases the pulse was followed by a 2-h chase in the presence of 1 mM uridine. 2.5×10^6 cells were removed, washed and lysed in 1.95 M NaCl on step gradients containing 1.95 M NaCl, spun (Beckman SW50.1 rotor; 15,000 r.p.m.; 45 min) to sediment the nucleoids on to the step and the percentage of ³H co-sedimenting with the nucleoids was determined ^{15,16}. Nucleoids were collected, diluted to 0.2 M NaCl, incubated with EcoRI and the proportion of labels remaining associated with cages was determined after filtration^{1,19}. A control experiment showed that >97% of the ³H but filtration^{1,19}. A control experiment showed that >97% of the ³H but none of the ¹⁴C could be detached from cages by ribonuclease.

nucleoids contain some elements of the cytoskeleton (that is, actin and intermediate filaments), the cytoplasmic RNA does not co-sediment with the nucleoids.

For the third control we studied Chandipura virus, a rhabdovirus with a single genomic RNA strand of negative polarity and whose reproduction is cytoplasmic²⁰. Plaque-purified virus²¹ was grown in chick fibroblasts (conditions and multiplicity of infection similar to those described in Table 1 legend so that cytopathic effects were visible after 7 h) in the presence of a concentration of actinomycin D (0.5 µg ml⁻¹ added 1 h post-infection) which suppresses nuclear RNA synthesis by >95%. When, at 4 h post-infection, cells were labelled for 10 min with ${}^{3}\text{H}$ -uridine (50 $\mu\text{Ci ml}^{-1}$), about 3.7 times more label was incorporated into infected cells than into mockinfected controls; thus, 73% of the labelled transcripts were viral, the remainder being the residual host transcripts. When such cells are lysed and spun, only 30% of the incorporated label co-sedimented with nucleoids; 70% was cytoplasmic and remained at the top of the gradient. Unlike nascent influenza virus transcripts, the transcripts of Chandipura virus are not associated with cages.

We have demonstrated that at early and late times during infection with influenza virus, at least 50% of the nascent transcripts in infected cells are viral and all are attached to the nuclear cage. They remain attached in the detergent and 2 M NaCl used to prepare nucleoids. We might have expected little host involvement in RNA-dependent RNA synthesis, especially as the infecting virus contains a polymerase which is capable of synthesizing its own mRNA in vitro 22,23. It is perhaps not surprising that nascent transcripts of positive polarity are cage associated because they are covalently coupled at their 5' ends to host-encoded sequences^{24,25}, which we have shown are themselves attached1. Attachment of nascent transcripts of negative polarity, which do not contain any host-encoded sequences, is more surprising. However, a complex picture of processing of nuclear transcripts is now emerging. Transcripts are attached to the nuclear cage as they are generated and subsequently as heterogeneous nuclear RNA²⁶⁻²⁸; later they are attached to the cytoskeleton as cytoplasmic message²⁹. (This cytoskeletal attachment is unstable in high salt concentrations.) There are

obvious practical advantages in tying a long RNA molecule to a larger structure during such a complex series of events as synthesis, capping, methylation, splicing, polyadenylation and translocation to the cytoplasm. There are additional problems associated with the regulated transcription and replication of the eight influenza viral segments and attachment could provide a structural basis for this. Therefore, attachment may play a central part in these processes and any viral nucleic acid subverting some, or all, of them, must also become attached.

We thank Professor H. Harris, Professor G. G. Brownlee and Dr B. S. Cox for their encouragement, Dr J. S. Porterfield and Professor D. H. L. Bishop for their help with Chandipura virus, and the Cancer Research Campaign, MRC and SRC for support. Wild-type Chandipura virus was from Dr C. R. Pringle.

Cytogenetic location and expression of collagen-like genes in *Drosophila*

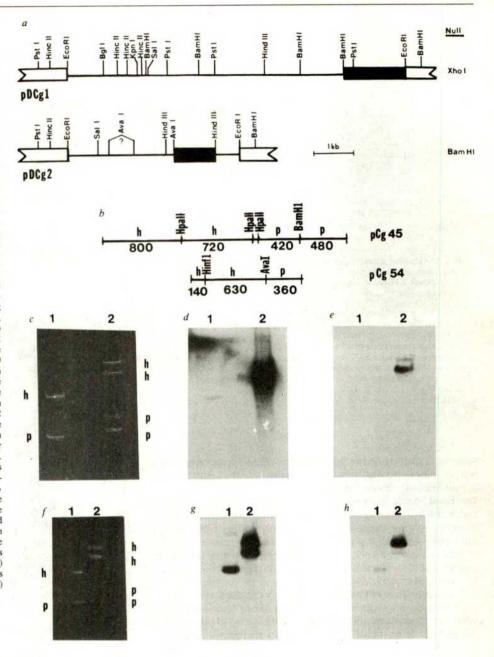

J. E. Natzle*, J. M. Monson† & B. J. McCarthy‡

Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, USA

Much of the present interest in vertebrate collagens stems from the important part which these extracellular, structural proteins play in developmental processes and tissue organization as well as from their complex gene structure. So far the only vertebrate collagen genes examined encode the constituent polypeptide (pro α) chains of type I procollagen, that is, the pro $\alpha 2(I)$ genes from chicken^{1,2} and sheep³, and the pro $\alpha 1(I)$ gene from mouse⁴. Recently, we have isolated several collagen-like genomic DNA clones from Drosophila melanogaster5. In addition to providing data on the evolutionary history of this gene family, studying Drosophila has distinct advantages for cytogenetic localization of genes and for defining the functional roles of individual collagens by the application of genetic techniques. Here we compare the hybridization patterns, cytogenetic localization and expression of two of the Drosophila clones, DCg1 and DCg2. Although they are cytogenetically unlinked, they share similar developmental RNA profiles.

Present addresses. * Department of Genetics, University of California, Berkeley, California 94720, USA, Zymos Corporation, 2121 North 35th, Seattle, Washington 98103, USA, ‡ Department of Molecular Biology and Biochemistry, University of California, Irvine, California 92717, USA

Fig. 1 Radioactive probes constructed from the Drosophila sequences DCg1 and DCg2 were hybridized to restriction digests of chicken collagen cDNA sequences to determine the regions of homology between the Drosophila chicken sequences. a, Restriction maps of DCg1 and DCg2. Open boxes represent pBR322 vector sequences flanking the inserted Drosophila DNA and solid boxes represent regions of Drosophila DNA that cross-hybridize to the chicken clone, pCg45. Radioactive probes representing the solid regions were made by ³²P nick-translation26 of the following restriction fragments purified from agarose gels by electroelution: pDCg1, 1.5-kb EcoRI/BamHI frag-ment; pDCg2, 1.2-kb internal HindIII fragment. b, Digestion with the appropriate restric tion enzymes divides the chick collagen cDNA insert sequences into discrete fragments that encode either the Gly-X-Y repeat involved in triple helix formation (h) or the carboxyterminal propertide region (p) of the pro α -chain^{6,7}. The pro α 2 clone (pCg45) can be cut with HpaII and BamHI to produce two fragments of 800 and 720 base pairs (bp) encoding regions participating in triple helix formation, and two smaller fragments of 480 and 420 bp representing the propeptide region (see lane 2 of c and f). The pro $\alpha 1$ clone (pCg54) can be cut by AvaI and HinfI into fragments of 630 and 140 bp involved in triple helix formation and a fragment (360 bp) encoding propeptide sequences (see lane 1 of c and f). c-h, The Drosophila probes were hybridized to Southern blots of the restricted chick pro α 1 and pro α 2 collagen cDNA sequences to determine whether the shared homology was localized in areas encoding the triple-helix forming (h) or propeptide (p) regions of the chick sequence. c-e, The DCg2 probe was hybridized to filters in a 50% formamide, 5×SSC hybridization solution26, and washed at 50 °C in 0.5 × SSC, 0.1% SDS; a long exposure (d) and shorter exposure (e) of the autoradiograph are shown. f-h, The DCg1 probe was hybridized as above and washed first at 50 °C in 0.5 × SSC (g) and then at 50 °C in 0.1 × SSC (h). The DCg2 probe hybridizes preferentially to one of the fragments (720 bp) encoding the triple-helix forming (h) region of Cg45 while the DCg1 probe hybridizes most strongly to the other fragment (800 bp) that encodes the triple helix-forming region.

The differences in hybridization of each Drosophila clone to two chicken collagen cDNA clones suggests that the Drosophila sequences represent different members of a family of related collagen-like genes. The isolation of these Drosophila clones was based on sequence homology with a heterologous hybridization probe, the cDNA clone pCg45, encoding half of the chicken pro \(\alpha 2(I) \) chain⁶. As shown in the restriction maps for the subclones pDCg1 and pDCg2 (Fig. 1a), the region of homology to Cg45 extends over only a portion of each clone. Hybridization of Cg45 to these designated subfragments is limited to the region of the cDNA clone encoding the Gly-X-Y sequences that participate in triple helix formation (the α -chain domain) (Fig. 1c-e). Each of the two Drosophila clones hybridizes preferentially to a different section of the chicken cDNA clone encoding the Gly-X-Y repeat (Fig. 1c-h). In addition, DCg1 shares more homology than DCg2 with the α-chain domain specified by a chicken pro a1(I) cDNA clone7 (Fig. 1c-h). Although the number of genetically distinct collagen chains in Drosophila is unknown, there is biochemical evidence in other invertebrates for multiple chain types⁸⁻¹⁵. Therefore the differences in hybridization of the Drosophila clones to the chicken pro $\alpha 1(I)$ and pro $\alpha 2(I)$ cDNA clones suggest that the

former represent structurally distinct collagen-like molecules. However, if the two sequences use different codons preferentially, as observed for other collagen genes^{4,16}, they may simply represent non-allelic copies of a gene encoding one collagen-like protein. DNA sequence analysis of DCg1 indicates that it may encode a segment of a non-fibrous collagen such as a basement membrane or cuticle collagen, or a novel collagenous protein⁵.

At moderately low stringency, the genomic hybridization patterns defined for *Drosophila* embryonic DNA by the chick sequence Cg45 and the two *Drosophila* sequences DCg1 and DCg2 are each composed of several cross-reacting species (Fig. 2). Although the three patterns are not identical, it is clear that they do overlap. The similarities are more apparent between Cg45 and DCg1 than between Cg45 and DCg2, supporting the idea that the *Drosophila* sequences may encode proteins of two different structural classes. The 1.2-kilobase (kb) internal *HindIII* fragment of pDCg2 (see Fig. 1) used as a probe in this experiment hybridizes to a single *EcoRI* genomic restriction fragment, but labels two *HindIII* genomic restriction fragments with approximately half the intensity of the *EcoRI* hybridization band. These data indicate that there are two closely related

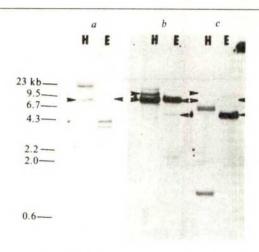

Fig. 2 Genomic hybridization patterns generated by Cg45, DCg1 and DCg2 sequences. Genomic DNA from *Drosophila* Canton S strain embryos (0–24 h) was digested to completion with either *HindIII* (H) or *EcoRI* (E), fractionated on 1% agarose gels and transferred to nitrocellulose filters²⁷. Each lane contained 5 μg DNA. ³²P-labelled probes were made from the cDNA insert of pCg45 by labelling with T4 DNA polymerase (Bethesda)²⁸ and from the DCg1 and DCg2 restriction fragments described in Fig. 1 by nick-translation²⁶. *a*, 1×10⁶ c.p.m. of Cg45 probe were hybridized at 37 °C (ref. 26) in the presence of 10% dextran sulphate²⁹ for 24 h. The filter was washed in 0.5 × SSC at 50 °C and autoradiographed for 4.5 days. *Drosophila* probes (2×10⁶ c.p.m.) from DCg1 (b) or DCg2 (c) were hybridized at 37 °C as in *a*, washed at 50 °C in 0.1×SSC, and autoradiographed for 2 days. The mobilities of *HindIII*-restricted λ phage DNA used as size markers are indicated. Some shared cross-reacting sequences are indicated by arrowheads.

sequences located on the same genomic EcoRI fragment, which may explain the size discrepancy between the EcoRI band present in both the phage isolate and our subclone (4.3 kb) and the EcoRI band labelled in the genomic hybridization experiment (5.6 kb). During cloning and propagation in the λ vector, a recombination event between the two regions of homology may have deleted a portion of the original genomic EcoRI fragment. Alternatively, an artificial EcoRI site may have been introduced into a larger genomic EcoRI fragment during the λ library construction.

The same Drosophila sequences that were used as probes in the above experiments were hybridized in situ to salivary gland polytene chromosomes. These experiments identified the cytogenetic locus of pDCg1 as 25C on chromosome 2L and the locus of pDCg2 as 19EF/20AB near the proximal end of the X chromosome (Fig. 3). Thus the two Drosophila sequences are located at separate, unique cytogenetic sites and are not part of one complex gene locus. The DCg2 sequence is located within or near a probable heterochromatin/euchromatin boundary. Other workers 17,18 have described active genes in analogous locations. The 25C locus for DCg1 is near a puff site in the 25AC region described by Ashburner¹⁹. This puff regresses in third instar larvae as ecdysone levels increase. This pattern of puffing is consistent with the developmental RNA profile of DCg1 described below. However, these similarities may be coincidental.

The accumulation of RNA transcripts homologous to the two *Drosophila* clones was measured in RNA populations representing sequential periods of the *Drosophila* life cycle (Fig. 4). A dot-blotting procedure was used in which aliquots of total RNA were immobilized on nitrocellulose filters and hybridized in probe excess (J.E.N. and B.J.M., unpublished observations). The maximal accumulation of homologous RNAs occurs during the first and second larval instars for both DCg1 and DCg2. RNA homologous to DCg1 is first detected during embryogenesis 12–15 h after oviposition, slightly preceding the first DCg2 hybridization signal. The presence of DCg2 transcripts extends beyond those of DCg1 into the third larval instar. RNA from cultured *Drosophila* Kc cells apparently contains transcripts

homologous to both DCg1 and DCg2. The hybridization and washing stringencies of these experiments demanded more precise base pairing than did the conditions used for the genomic blots in Fig. 2, and no significant cross-reaction occurred between DCg1 and DCg2 as measured by the DNA dots on each filter. The accumulation of DCg1 and DCg2 transcripts is clearly under developmental control.

Ultrastructural, biochemical 9.11,20 and genetic 21 studies in insects have demonstrated the existence of a basement membrane around internal organs in larval and adult stages, between the epithelium and muscle layer in larvae and also enveloping the imaginal disks. The developmental RNA profile that we have determined for the *Drosophila* sequences is consistent with the observed time courses for some of these processes, such as the initiation of internal or epithelial basement membrane formation during embryogenesis and early larval development. The pattern is equally consistent with larval cuticle deposition, although collagen-like proteins have not been reported to be components of this larval structure 22. These

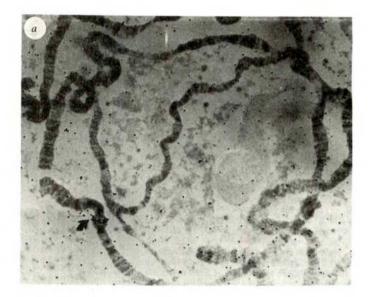

Fig. 3 In situ hybridization of DCg1 and DCg2 to Drosophila polytene chromosomes. ³H-cRNA probes were transcribed in vitro from DCg1 and DCg2 and hybridized at 60 °C to polytene chromosome squashes²⁶. Each slide received 4×10⁵ c.p.m.; 14-day exposures. a, DCg1 hybridization over 25°C on chromosome arm 2L; b, DCg2 hybridization over 19EF/20AB near the proximal heterochromatic region of the X chromosome. ×300.

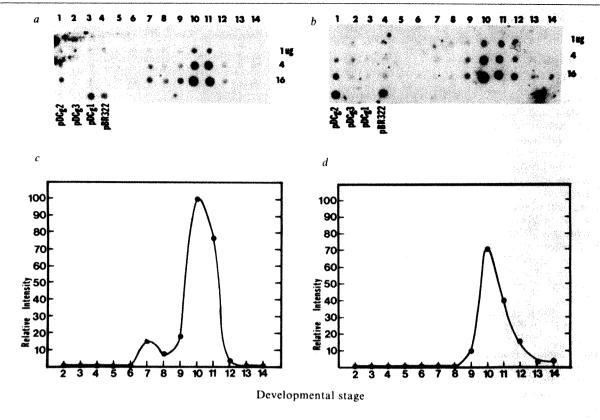

Fig. 4 Developmental mRNA profile of DCg1 and DCg2 expression. Total RNA was prepared from different *Drosophila* developmental stages³⁰ and immobilized on to nitrocellulose paper by loading aliquots in $20 \times SSC$ from a capillary pipette³¹. Three RNA concentrations (1, 4 and 16 μ g) were used for each developmental stage. Each filter also contained control dots of the plasmids containing the Drosophila collagen-like sequences. Filters were hybridized by applying sufficient probe sequences to generate a local 10-fold sequence excess over the highest estimated target sequence concentration in any dot (J.E.N. and B.J.M., unpublished results). Hybridizations were done at 42 °C in 50% formamide, $5 \times SSC$ hybridization solution 26 and the filters were washed in an equivalent solution at 50 °C after 24-30 h hybridization. The figure shows autoradiographs of RNA dot blots hybridized with DCg1 (a) or DCg2 (b) sequences. c, d, The autoradiographs were quantitated using an LKB soft laser scanning densitometer. The maximum absorbance was calibrated for the most intense hybridization signal of DCg1 and other signals are expressed relative to that signal. The developmental stages represented are: 1, Kc cells; 2-9, periods during embryogenesis following oviposition by 0-2, 2-3, 3-6, 6-9, 9-12, 12-15, 15-18 and 18-21 h, respectively, 10-12, First, second and third instar larvae, respectively, 13, White prepupae. 14, Mid-pupation. An identical filter hybridized with pBR322 vector sequences showed hybridization only to control dots (data not shown).

sequences may also represent proteins containing a small, triplenelical region such as Clq23 or acetylcholinesterase24, although partial sequence data make this possibility unlikely for DCg1 ref. 5). Neither pDCg1 nor pDCg2 show evidence of in situ sybridization to the Drosophila acetylcholinesterase locus at 37E1-5 (ref. 25).

Characterization of collagen genes in invertebrates such as Drosophila will hopefully allow genetic analysis of collagen structure and expression as well as providing insights into evolutionary relationships of vertebrate collagens.

We thank H. Boedtker for providing the chicken cDNA clones pCg45 and pCg54; J. Fristrom and T. Kornberg for illowing us to use their fly facilities for collection of embryos, arvae and pupae; and T. Maniatis for providing the Drosophila ecombinant λ phage library used in screening. This work was supported by an NIH training grant to J.E.N. and an NIH grant o J.M.M. and B.J.M.

Errata

In the letter 'Chorus-related electrostatic bursts in the Earth's outer magnetosphere' by L. A. Reinleitner, D. A. Gurnett and D. L. Gallagher, Nature 295, 46-48 (1982), in Fig. 1 legend the words 'features of the chorus related electrostatic bursts. The slight inter-' have been repeated. Thus the second sentence should read 'The slight interference from 1738:45 to 1739:17 UT (also in Fig. 3) is from the ISEE electron density experiment.

In the article 'Protochordate allorecognition is controlled by a MHClike gene system' by V. L. Scofield, J. M. Schlumpberger, L. A. West and I. L. Weissman, Nature 295, 499-502 (1982), in Table 4 legend the percentage fusible progeny yielded by crosses where no alleles are shared should be 75%, not 7.5%

In the letter 'Stereochemistry of iron in deoxyhaemoglobin' by M. F. Perutz, S. Samar Hasnain, P. J. Duke, J. L. Sessler and J. E. Hahn, Nature 295, 535-538 (1982), in the final paragraph of page 537, references 14 and 12 should read 15 and 11, respectively. On page 538 the reference cited at the top of the second column of text should be 12, not 13.

MATTERS ARISING

The ν_3 fundamental band of the methyl radical

IN discussing near-IR absorption bands in IRS7, Allen and Wickramasinghe¹ remark that "laboratory data are not available for even quite simple, incompletely bonded molecules (for example, CH₃) such as might be found in the interstellar environment".

We have recently performed a laboratory measurement of the ν_3 fundamental band $(\nu_0 = 3,160.820 \text{ cm}^{-1})$ of CH₃ in absorption using a difference-frequency laser². The most prominent feature in the spectrum is the ${}^{\dagger}Q_0(N)$ (N=2,4,6,...)sub-branch. The transition frequency of strongest line, $^{r}Q_{0}(2),$ the $3,154.7459 \text{ cm}^{-1} \ (= 3.16983 \ \mu\text{m})$. Other strong lines at (300 K) are calculated to be: 3,101.045, 3,128.548, 3,199.730, 3,217.754, and 3,224.396 cm⁻¹. However, none of the prominent features reported by Allen and Wickramasinghe seem to fit our observed transition frequencies.

The methyl radical is expected to be an important species in certain interstellar sources³. In particular, estimates of the abundance of CH₃ in the atmosphere of the nearby carbon star IRC +10°216 indicate that its abundance relative to CO is $\sim 10^{-4}$ (ref. 4 and personal communications from E. M. McCabe, R. C. Smith and R. E. S. Clegg, and A. Kinney). Thus the methyl radical should be detectable in this source and we plan to conduct an IR search for it in the very near future.

Saturn's rotation period

CARR ET AL. have inferred Saturn's rotation period from data recorded by the Voyager-1 Planetary Radio Astronomy (PRA) instrument. They constructed profiles of the received power in the coordinate frame of the Saturn longitude system (SLS) determined by ourselves? After comparing profiles made from month-long spans taken ~7 months apart, Carr et al. attributed a longitude shift to a 2-s error in the SLS rotation period.

Some problems in the work of Carr et al, affect the validity of their result. First is the precision of their method. From basic statistics we would expect the standard deviation in the individual rotation period determinations to scale with the square root of the number of samples. Thus, as Carr et al, used 2 months of data whereas we used 8 months, the former's individual standard deviation should be no better than root (8/2) times that of the latter, or ± 14 s. In addition, this value should vary with observing frequency owing to the change in emission occurrence probability with frequency. The rotation period at 500 kHz cannot be determined nearly as well as at 150 kHz because the occurrence probability is at least a factor of 4 lower at 500 kHz (ref. 3).

Using PRA data, we attempted to assess the inherent uncertainty in their method. We compared flux density longitude profiles generated over different time intervals, but at the same frequency. For example, comparing the longitude profile made at 346.8 kHz from data only 1 month apart, we found a 70° shift, which would correspond to an uncertainty of 15 s over the \sim 7 month time span used by Carr et al. We repeated the analysis at 155 kHz and at 97 kHz where we found that individual profiles were reliable to \pm 10 s and \pm 17 s, respectively. These are only estimates, of course, as we have not done an exhaustive analysis, but they are representative of the inherent uncertainty in determining the rotation period by aligning longitude profiles. Our error analysis² is sensitive to these large shifts, however, because it encompasses the entire span of data.

Second, we question the practice of combining results from several different frequencies to improve the precision of the determination. While this would be an acceptable statistical procedure in other circumstances, we have determined that the radio bursts are well correlated over a wide frequency range, and are never completely uncorrelated. Thus, receiver channels within the radio emission band contain non-independent, correlated information that cannot be averaged together, as was done by Carr et al., to reduce statistical fluctuations. We believe that conservative adherence to statistical principles would dictate that only one completely independent rotation period determination is possible using a single PRA data set.

Finally, and perhaps most importantly, the longitude profiles of Carr et al. were generated in a coordinate system locked to the Saturn-spacecraft line. However, because Voyager-1 moved 6° relative to the Saturn-Sun line during the 7-month analysis interval in question, the data should instead be organized in fixed (sub-

solar) coordinates. This angular shift will manifest itself in the longitude profiles, and hence in the rotation period, and should be taken into account. In short, given the inherent imprecision of the histogram method, the Carr et al. determination is certainly not statistically inconsistent with ours.

M. L. KAISER M. D. DESCH

Planetary Magnetospheres Branch, Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

- Desch, M. D. & Kaiser, M. L. Geophys. Res. Lett. 8, 253-256 (1981).
- Kaiser, M. L., Desch, M. D. & Lechcheux, A. Nature 292, 731-733 (1981).

CARR ET AL. REPLY—The strongest objection of Kaiser and Desch to our results is essentially that we used histograms plotted as a function of the saturnian central meridian longitude of the spacecraft instead of that of the Sun in our cross-correlations. When our oversight is corrected, we find our three rotation period measurements to be only 1 s less than they were before, and their average to be 3 s instead of 2 s less than the SLS value. This small correction does not change the situation materially.

We agree that the SLS rotation period measurement is probably more accurate than ours, but we do not believe that the difference in accuracy is large. The agreement to within 3 s increases confidence in both determinations. Our accuracy can certainly be improved by a better choice of data interval for the first histogram in each pair. We do not agree with the contention of Kaiser and Desch that little is to be gained by using data from several channels instead of just one. The redundancy resulting from the high correlation between pairs of closely spaced channels indeed tends to reduce their individual contributions to the overall precision, but is beneficial in other ways such as minimizing the effects of data gaps and of interference incorrectly identified as Saturn. The best method, in our opinion, would be to calculate the rotation period using data from each of about 10 selected channels separately by the method of Desch and Kaiser, and then to combine these values, appropriately weighted, into a single average.

BOOK REVIEWS

Prehistoric geometers?

J.N. Graham Ritchie

STONE circles and standing stones have perhaps a greater fascination than most other classes of prehistoric monument, not because we understand more about them, but because we know less. With hill-forts, burial mounds and hut-circles we can readily appreciate their possible role within society; with stone circles and standing stones this is not so, and excavation does not add greatly to an understanding of their function. The archaeologist may discover burials at the centre of a circle or cremated bone within the packing of the socket of a standing stone, but he cannot say that burial was the only function of such sites, and the suggestion that circles may have been central places for the dissemination of legal or religious lore is a woolly alternative.

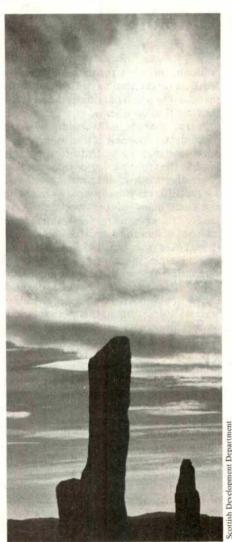

The most comprehensive interpretation of many megalithic remains has been put forward by Alexander Thom in a series of papers and books resulting from years of painstaking fieldwork and observation, particularly in Scotland, Wessex and Brittany. Thom has suggested the use of a standardized unit of length in their construction and a knowledge of complex geometry in their layout. Further, he has postulated that the erection and positioning of stones and cairns was designed to allow sophisticated observation of the major celestial bodies, including the prediction of eclipses. Thom's work, together with the influence of Gerald Hawkins and J.B. White's volume Stonehenge Decoded (Souvenir, 1965) in which the famous circle was described as an observatory, have created a climate of popular opinion in which the concept of prehistoric scientists and astronomers is accepted without question. How can you prove, the archaeologist is asked, that such people did not exist, or are less credible than purveyors of social or legal wisdom - classes in prehistoric society that seem to be taken for granted.

Perhaps it takes a scientist to examine a potential prehistoric colleague; in this masterly volume, Douglas Heggie, a mathematician and astronomer in the Department of Mathematics at the University of Edinburgh, has explained clearly the data on which prehistoric science rests. It is as though Heggie, the teacher, has returned to prehistoric times to test the knowledge of a student of science and astronomy. The possible range of the background information that the student might have is carefully set out in non-scientific language; whether the

Megalithic Science: Ancient Mathematics and Astronomy in North-West Europe. By Douglas C. Heggie. Pp.256. ISBN 0-500-05036-8. (Thames and Hudson: 1981.) £12, \$27.50.

student possesses this knowledge is then judiciously weighed and statistically tested, but the conclusion — to the sadness I suspect of the examiner and the reader — is that he did not have many of the skills that had been attributed to him.

Heggie has set out the evidence for the units of length which may have been used in the construction of stone circles, and has explored the ways in which the sometimes deliberately eccentric ground-plans of such sites were designed. Using a rigorously

Clouded past — part of the stone circle at Callanish, Lewis, in the Western Isles.

statistical approach Heggie finds little evidence for a highly accurate unit of length (his italics), and while accepting that Thom's classification for the shapes of megalithic sites is helpful, he questions the need for any knowledge of Pythagorean triangles and of π in their layout. Heggie's conclusions on astronomical matters are equally tentative: that, while prehistoric man knew something of the movements of the Sun, and possibly the Moon, his role was that of an observer rather than theoretician.

Such a verdict does not lessen the achievements of early man as an architect and engineer, and perhaps increases the importance of those particular aspects of his astronomical knowledge that are found to exist. Indeed our appreciation of his strengths in empirical science are increased by such careful examination; perhaps most remarkable is the orientation of the passage grave of Newgrange, County Meath, so that the rising Sun of the winter solstice bathes the rear chamber with light, not through the entrance to the tomb, but through a specially designed opening, known as the "roof-box". Thus respect for the many empirical skills demonstrated by the designers and builders of stone circles and alignments is not called into question by doubts about their appreciation of theoretical science or involvement in astronomical observation to a high degree of complexity.

A subject rarely discussed in archaeoastronomical literature, and not considered in detail by Heggie, is that of the interpretation of the archaeological evidence itself. Distinct classes of stone monument can be outlined, some with a long chronological span, others covering shorter periods, and still other groups, such as simple upright stones, the dates of which remain quite unknown. Archaeologically it is important to distinguish between those sites where the upright stones delimit an open area, such as most stone circles, and those where the stones have acted as the retaining kerb of a burial cairn. The complexities of megalithic sites can be demonstrated most fully in terms of structural alteration over perhaps two millennia by the recently excavated site of Temple Wood in Argyll and our knowledge of this sequence is now much greater than that outlined in this volume. Where astronomical observations have been to the highest standard (in Thom's work this is not in question), it is unfortunate that the archaeological interpretation of archaeo-

astronomers has not been as scrupulous indeed some stone alignments given astronomical interpretations may be no more than the foundation stones of turf field-walls where the ephemeral materials have weathered away. The lack of scientific knowledge for which field archaeologists are so often criticized has led to a disregard for those skills of observation and site interpretation that are their own stock in trade. A reassessment of the archaeological content of Thom's work - for in the final analysis it is on the stones themselves that the hypotheses rest — would have been a valuable adjunct to Heggie's reexamination of the data.

It is important to stress that this discussion is concerned geographically with north-west Europe and chronologically with the period between about 4000 BC and 1000 BC. Considerable momentum for the study of ancient astronomy in other parts of the world has resulted from Thom's work, though not directly stemming from it, and the levels of observational astronomy practised in other societies will clearly have a bearing on what we expect

from our present vision of prehistoric Britain. Nor will all scholars view the evidence in the same way — there is no simple "standard archaeological model", no "orthodox archaeological picture" to compare with a map of the stars; most models change with new discoveries and new approaches, either imperceptibly or radically.

Few debates can have been as measured and carefully presented. Professor Thom and his son Dr A.S. Thom have outlined in clear steps and precise documentation the basis of their findings on megalithic measurements, shape, astronomy and calendrical matters. Dr Heggie has used this material and considered it in mathematical, astronomical and statistical ways, and has presented his own findings with caution and fairness. His ability to disagree without minimizing the work of others is perhaps his greatest personal contribution.

J.N. Graham Ritchie is an Archaeological Investigator with the Royal Commission on the Ancient and Historical Monuments of Scotland.

Virus variety for plant pathologists

Milton Zaitlin

Handbook of Plant Virus Infections: Comparative Diagnosis. Edited by Edouard Kurstak. Pp.943. ISBN 0-444-80309-2. (Elsevier/North-Holland Biomedical: 1981.) Dfl.395, \$192.75.

A GIVEN virus often causes disease in several different plant species. Thus although well over a thousand plant virus-induced diseases are known, they are caused by only several hundred viruses (350 are considered in this handbook). This situation is further clouded by the assignment of unique names to identical diseases discovered independently.

A good conceptual framework for virus classification is therefore essential. Fortunately, ten years ago a rational approach to the problem was put forward by a small group of plant virologists in which viruses were collated into 16 "affinity" groups based on their morphology, particle composition, mode of transmission and so on. Quasi-official sanction has been given to this movement by the International Committee on the Taxonomy of Viruses, which has undertaken responsibility for the classification of viruses in general. The classification is periodically reviewed, modified and extended, and every three years, after the meeting of the ICTV, the revised classification is published as a small volume.

Edouard Kurstak's handbook follows the ICTV classification scheme, providing detailed individual chapters on virus groups, each prepared by a specialist. It is an extremely useful reference work. In addition, there is a perceptive chapter by R.I.B. Francki dealing with plant virus taxonomy in which he outlines the basis for the classification scheme.

A true "handbook" should provide as much data as possible if it is to serve as a good reference work. Unfortunately this book suffers to some degree from uneveness in the depth of information covered for the different virus groups. As might be expected, many of the specialists have tended to emphasize their immediate interests within their assigned group, and they cover the available information beyond their specialities with differing emphasis. As one extreme example, six pages of text are devoted to a detailed listing of the hosts of the hordeiviruses, whereas little information is given for some other groups with extensive host ranges (such as the potyviruses) where such information is available. The editor is not himself a plant virologist and it is understandable that he would have to rely heavily on the judgements of the individual authors as to which topics should be emphasized.

All in all, the book is excellent and would be a welcome addition to the bookshelves of agriculturists, and to plant pathologists in particular. It is especially well-produced on quality paper and contains a great deal of tabulated information and many good photographs. Certainly, I will treasure my complimentary copy.

Milton Zaitlin is a Professor of Plant Pathology at Cornell University.

Something in the air

J.E. Lovelock

Atmospheric Sulfur Deposition: Environmental Impact and Health Effects. Edited by David S. Shriner, Chester R. Richmond and Steve E. Lindberg. Pp.568. ISBN 0-250-40380-3. (Ann Arbor Science Publishers/Butterworth: 1981.) \$29.50, £17.

As in the workings of a Greek tragedy, there is nothing now to indicate the discomforts that lie ahead as heedlessly we burn fossil fuel and CO2 grows ever more abundant in the air. But this is not so for the small percentage of sulphur in these fuels; of all consequences of mankind's industrial activity on the planetary environment, none are more obvious than those caused by the emission of sulphur compounds to the atmosphere. Their presence is objectionable on scales running from the stench of reduced sulphur compounds locally released, to the planetaryscale effects on climate of the Junge stratospheric sulphate aerosol. In between these lie other consequences, such as the breath-taking lethal smogs which once beset London and the translucent sulphate aerosol which obstructs the summer sunshine over whole regions. Worst perhaps is the destruction wrought by acid deposition which diminishes life in the forests, lakes and rivers of much of the Northern Hemisphere.

Atmospheric Sulfur Deposition is an unusually tight and well-edited collection of papers from a symposium held at the Oak Ridge National Laboratory in Tennessee. It moves from the consideration of the costs and benefits of controls and their legislative implementation to the little that is known about natural sources of sulphur gases in North America, and then to the emissions from the technosphere. The atmospheric chemistry, the transfer across the interfaces with the land, and ocean, the effects good and bad on man-made and natural ecosystems, all are taken into account.

It is a book for those sizeable ranks of professionals concerned with national and regional air pollution problems. These include scientists and administrators in government and industrial service, and also legislators and regulators. For this group it will provide a very credible addition to their working knowledge of the sulphur pollution problem. The book is not primarily intended for those scientists curious about the great natural cycles of the elements and who might wish to know more about the part played by sulphur. Even so, this group also might well benefit

Missing from the review of recent textbooks of invertebrate zoology (Nature 295, 482; 1982) was mention of Peter Calow's Invertebrate Biology: A Functional Approach. Published by Croom Helm, the book costs £11.95 (hbk), £5.95 (pbk).

from reading it, for it establishes the context in which so many papers on the atmosphere and on atmospheric pollution are written, a context very different from the rarefied altitudes of academic aeronomy.

The natural cycles of the elements are closely linked and it is usually difficult to consider one of them in isolation. This restriction limits the value of the papers on the natural sources, but in any case information about natural sulphur emissions is still very meagre. The presence in the environment and the release of such compounds as COS, CS₂ and alkyl sulphides has only very recently been established. To be certain of the extent of their contribution to the natural cycle of sulphur we must wait until expeditions have measured the abundance and release rates of these transient and important compounds. It is not enough to rely on the few measurements made at sites close to the northern industrial regions. To be representative of the sulphur cycle in space and time we need measurements from all parts of the planet. made so as to include the diurnal, seasonal and secular variations. It is also possible that other sulphur compounds are yet to be discovered. Indeed, the presence of methanesulphonic acid in the sulphate aerosol has been reported. This compound, an end-product of the atmospheric oxidation of biogenic sulphur gases, may be a useful indicator of the proportion of acid deposition from these sources as compared with that coming from combustion.

There is a tendency in the book to assume that the agricultural ecosystems which cover most of the land surface are "natural" and that emissions of sulphur gases now measured from the soil are the same as those from the pre-industrial and pre-agricultural ecosystems. It now seems at least possible that the contemporary releases of sulphur gases are the product of a pathology and a consequence of a surfeit of sulphur and of other nutrients. This comment applies also to the rivers, estuaries and salt marshes which are the recipients of the run-off from agricultural and urban sewage.

Truth is said to be the first casualty of war. Looking back on the parallel environmental issue of the ozone war it seems also that scientific objectivity does not flourish in the sparring which precedes legislation and regulation. Inevitably, any collection of scientific papers from a meeting about an atmospheric topic whose objectives are national rather than global will reveal some limitation of this kind. This book commendably has overcome such a tendency to parochialism; thus the European dimensions of the acid deposition problem are well represented, and an attempt is made to link with more general scientific aspects through papers on the natural sources of sulphur gases.

Antibiotics at work

H.R. Perkins

The Molecular Basis of Antibiotic Action, 2nd Edn. By E.F. Gale et al. Pp.646. ISBN 0-471-27915-3. (Wiley: 1981.) £35, \$78.

SECOND editions can represent a special problem for reviewers, particularly if the movement in the subject matter (or worse. in the presentation of it) has been slight. Let me say at once that any difficulties in reviewing this particular production have arisen from precisely the opposite cause, namely that the nine years separating it from its predecessor have seen great advances in ideas about how antibiotics work. Even by the exercise of what must have been miracles of compression, the authors, all members of what one might term the Cambridge School of antibiotic investigators, have only succeeded in containing their subject within some 50 per cent more pages than before. That they have done so is a great credit to them; the book remains readable and transportable. essential characteristics of any text that has not become enshrined as an encyclopaedia.

The form of presentation remains unchanged. A general introduction to the basic concepts of antimicrobial substances is followed by logical and extensive chapters centred around the major targets of action, namely microbial wall synthesis, membrane function, nucleic acid synthesis and ribosome function. A consideration of bacterial resistance to antibiotics follows and the epilogue is entitled "Perspectives". The unifying approach is very valuable to the reader, who might be anyone from an honours microbiology student with an exceptional (or heavily directed) thirst for knowledge to a research worker seeking a detailed introduction to the field. Each chapter is well illustrated with tables and figures, and has a bibliography so generous and so recent that only an aggrieved author failing to find his own gems therein could possibly complain.

Of the three volumes covering the same general field of interest that I have reviewed recently, this is the most "up-market" in intention and there is no doubt that it achieves its object admirably. It will appeal particularly to professional chemists, biochemists and microbiologists who require a clear presentation of the latest word on the interaction of antibiotics with their targets. The coverage of information that has accrued since the first edition is impressive. When one considers that, for instance, transposons were unheard-of then and penicillin-binding proteins had not been isolated or characterized, one realizes the extent of progress that has been made in our understanding of the molecular mechanisms underlying antibiotic action and microbial resistance. Whoever purchases the present volume has an exceptional opportunity to rectify any deficiencies in his fund of information.

Ultraviolet Radiation in Medicine

Medical Physics Handbooks 11

BL Diffey

A concise introduction to the medical uses and biological effects of ultraviolet radiation (UVR) emphasising the practical nature of the subject. Separate chapters are devoted to the observable biological effects of external UVR exposure on the human eyes and skin; to the therapeutic, diagnostic and nonclinical applications in medicine; and to recent studies of personal exposure to environmental UVR including current safety standards for occupational exposure. Other chapters discuss natural UVR, the production of artificial UVR, the properties of various optical components and radiation dosimetry in this region of the spectrum.

Instrument Science and Technology

Volume 1

B E Jones (ed)

The first volume in a series on measurement and instrumentation. concentrating on the general principles and concepts of the subject and demonstrating how their systematic organisation offers a more unified understanding of this multidisciplinary field. The 13 chapters are selected from a series of educative articles originally commissioned by the Editors of Journal of Physics E: Scientific Instruments. They reflect current thinking on topics that are fundamental to all instruments and provide an authoritative guide and reference work on important aspects of the subject.

Adam Hilger Ltd

Techno House Redcliffe Way Bristol BS1 6NX England

Only if he wishes to know about developments in the antiviral field is he likely to go away more or less empty handed, but since the authors have largely, though not by any means entirely, confined themselves to "antibiotics" in the strict sense, this particular deficiency may be easily forgiven.

H.R. Perkins is Professor of Microbiology at the University of Liverpool.

Truncation at length

Francisco J. Ayala

Genetic Variability. By Christopher Wills. Pp.312. ISBN 0-19-857570-X. (Clarendon/Oxford University Press: 1981.) £24, \$49.50.

THE existence of inheritable variation is, as Darwin saw it, a necessary condition for evolution. The genetic variants present in a population at a given time define the evolutionary changes that are possible in the population. It has become established during the past two decades that populations of all sorts of organisms store an enormous wealth of genetic variation. In this book, Christopher Wills, a distinguished population geneticist of the University of California at San Diego, deals only in passing with the issue of how much variation is there, but explores in depth the mechanisms that account for the variation

This is a roman à clef. Wills's argument is that genetic variation is maintained largely by natural selection operating according to the truncation model. We may envisage the distribution of organisms according to their phenotypic fitness. A certain proportion of the organisms will survive and reproduce. According to the truncation model, the fitness value below which no survival occurs is not absolute but depends on the actual fitness distribution. The implications of truncation with respect to many central problems of population genetics are investigated at length, and most are published here for the first time this is undoubtedly the most significant contribution of the book. Among the important conclusions reached, one is that the gene is the unit of selection (Chapters 8 and 9). With truncation, the strength of linkage disequilibrium in outbred populations is not a function of selection but of the population size.

According to Wills, the most compelling evidence in favour of truncation selection

François Jacob's The Logic of Life: A History of Heredity (reviewed as The Logic of Living Systems in Nature 251, 81; 1974) has been reissued by Pantheon Books, New York. The book includes a new preface by the author, and costs \$7.95 in paperback.

is negative. If the fitness effects of each locus interact multiplicatively, then the maintenance of multiple polymorphisms would require a considerable segregational load — "highly homozygous populations should be extremely unfit' Astonishingly, on the following page Wills states that this is "contrary to observation". This ignores a number of experiments (e.g. M.L. Tracey and F.J. Ayala, Genetics 77, 569-589; 1974) showing that, when fitness as a whole is measured under population conditions, the inbreeding depression is enormous sufficiently large to account for hundreds of polymorphisms even if fitness interactions are multiplicative.

Wills asserts that whether or not most genetic variation is selectively neutral is a question "impossible to resolve, since it is impossible to prove the absence of something" (p. vii). This last phrase is obviously wrong, since I can prove to the

satisfaction of any reasonable person that there is no 747 Boeing airplane in my office. Most importantly, the statement misconstrues the aims and methods of science. The neutrality theory has been extremely fertile because it makes certain predictions about genetic variation, rates of evolution and so on. If such predictions were correct, the theory would be corroborated. Natural selection might be involved, but if it could be ignored in accounting for the relevant phenomena. there would be no reason to incorporate it in our explanations. One need not take into account the craters of Venus when explaining planetary motions. The point is a substantive one: the only hypotheses and the only parameters that are acceptable in science are those that are necessary in order to account for empirical phenomena.

Francisco J. Ayala is Professor of Genetics at the University of California at Davis.

A time and place for fire and brimstone

Peter J. Smith

Volcanoes of the World: A Regional Directory, Gazetteer, and Chronology of Volcanism during the Last 10,000 Years. By T. Simkin et al. Pp.248. ISBN 0-12-787478-X. (Hutchinson Ross: 1981.) \$19.75, £13.20.

PEOPLE have been compiling lists of volcanoes since at least 1650, when Varenius tabulated 27 examples. Two centuries later, Humboldt raised the total to 407; and, when complete, the IAVCEI's Catalog of Active Volcanoes (begun 1951) will contain details of about 900. The magnificent Smithsonian Institution volume under review here, however, lists no fewer than 1,343 volcanoes known or likely to have been active during the Holocene and 5,564 dated eruptions from about 8300 BC onwards, all arranged regionally and chronologically, respectively, in two large tables, to which are added a gazetteer and a bibliography.

Volcanoes of the World is thus the most complete and easily accessible compilation of volcanoes and volcanic activity now available, although the authors themselves hardly dare breathe the word "complete" in this context because their listings are anything but. For a start, most volcanism takes place on the sea floor and almost all of that goes unnoticed. Even on the continents, however, there are still regions in which much volcanic activity goes unrecorded; and if that can happen in a highly populated world shrunk by modern communications, how much more extensive must have been the omissions of the past. Indeed, Simkin and his colleagues demonstrate graphically that both the total number of known volcanoes and the

number of known active volcanoes have increased roughly exponentially over the past 600 years, which suggests either that the Earth is about to be overwhelmed by volcanic activity or that the perceived volcanic state of the planet is highly dependent upon reporting efficiency.

Under such circumstances, attempts to correlate known historic volcanism with other phenomena must be undertaken warily. Even so, the compilations at the heart of this volume will be a boon to a remarkably wide range of scholars quite apart from geologists. Biologists interested in colonization will find here the 96 eruptions known to have formed islands; glaciologists can easily pick out the 15 volcanoes with known subglacial eruptions; agriculturalists may like to know of the 181 volcanoes with eruptions known to have destroyed arable land; climatologists will look for those volcanoes known to have ejected particularly large amounts of ash and dust into the atmosphere; anthropologists might examine the listed eruptions known to have severely affected communities; and so on.

In short, Volcanoes of the World is, a splendid work of considerable interdisciplinary value and will become even more so if, as the authors hope, feedback from readers and other interested parties enables some of the many gaps to be filled. For this is not a one-off job but the first step in a continuing attempt to build as extensive a file as possible on the statistical aspects of the world's volcanism.

Peter J. Smith is Reader in the Department of Earth Sciences at the Open University, Milton Keynes, and editor of Open Earth.

Mycotoxins in South-East Asia?

The US government says that chemical weapons have been used in Indo-China, but its evidence falls short of proof. Even so, there is a case to be answered. How?

Last week's account by the State Department of chemical warfare in South-East Asia is a little like the discovery of quasars: something is undoubtedly going on, but it is impossible to tell just what. Part of the difficulty is that there is so little objective evidence. The principal allegation (see Nature, last week) is that the Vietnamese have been using chemical weapons of some kind in the wars in which they have been or are still engaged in Laos and Kampuchea (Cambodia), that the chemicals concerned include toxins of the kind produced during the growth of fungi of various Fusarium species and that these have been manufactured in the Soviet Union. The allegation, already vigorously denounced as "propaganda" by the Soviet news agency TASS, was first made public by Mr Alexander Haig in Berlin last September, but was at the time almost entirely unsubstantiated. Since then, scraps of information have been squeezed like blood from a stone from the State Department. Last October, the State Department gave the ad hoc group of experts set up to investigate the charges by the United Nations the results of the chemical analysis of samples of vegetation and other materials said to have been collected from Laos and Kampuchea. Now, it seems, there is more to say. The State Department clearly thinks it has evidence with which to prove its case. But only four samples of supposedly contaminated material have so far been analysed in the laboratory. The circumstances are exactly analogous to those in the early days of the quasars, when the implications of a meagre stock of data were clearly so huge that people could not summon up the fortitude to follow the prudent course — to wait for more data to accumulate. What, in these circumstances, is to be made of the State Department's report?

Although there are some numbers to play with, anecdotal evidence remains the most compelling part of the State Department's case. Reports of interviews with refugees from Laos and Kampuchea now in camps in Thailand have several strikingly common themes. Over a period of five years, they say, villages in central Laos and on the Kampuchean border with Thailand have been attacked with sprays, bombs or rockets releasing toxic agents. The heads of the rockets are said to have released red, blue or white smoke, while the sprays are now widely known as the causes of "vellow rain". The reports of the damage done to people are too many to be overlooked — or to have been fabricated. Nausea, dizziness and respiratory and circulatory troubles are the milder symptoms. Bleeding gums and other haemorrhagic phenomena are common. Statements that the corpses of those who have died are often bloated, and that their digestive tracts have rapidly become bloated, are a common theme in the reports of these first-hand accounts of attack from the air. And the State Department's star witness, a Vietnamese pilot who defected in 1979, has given such a specific account of how he carried out air attacks with unusual and presumably toxic

US contributors please note

From now on, authors in the United States and Canada should send their manuscripts either direct to London or to the Washington office, whose new address is *Nature*, 991 National Press Building, Washington, DC 20045; manuscripts should no longer be sent to *Nature*'s New York office.

weapons that those wishing to declare it false could fairly be asked to provide a specific and not a general denial.

Like all anecdotal evidence, of course, accounts such as these, however gripping, do not constitute proof. Interviews conducted by intelligence officers in far-away refugee camps do not have the objectivity even of the kinds of conclusions that emerge from examinations carried out by lawyers in courts of law. Indeed, in South-East Asia, the process of gathering verbal evidence must have been made even less certain by the difficulty encountered by the United Nations expert group on its flying visit to Thailand at the end of last year — the need to translate from a local dialect into Thai and from that into English. From the evidence now published, there is no way of telling how far witnesses may have been led to a desired tale by the questions asked of them, no simple way of making sense of statements that do not ring true (such as the assertion that yellow rain was sprayed from a height of 7,000 feet) and no simple way of being sure that the time-course of the conditions caused by the supposedly toxic chemicals were accurately described. The weight of the verbal evidence that toxic weapons have been used in South-East Asia therefore rests on the amount of it, not on its quality.

Because of such doubts, objective scientific evidence is potentially crucial. Here the difficulty is that there is far too little of it. Only four samples of material have so far been analysed for trichothecenes, the toxins produced by Fusarium species. According to the laboratory of Dr Chester J. Mirocha of the University of Minnesota, where the analyses have been carried out, the figures given in the State Department's report represent the proportions of trichothecenes in the whole bulk of the samples which have been analysed, so that if a leaf or water has been contaminated by some artificial external agency, the concentration of the toxins in that source must be higher, probably very much higher, than the concentrations that have been reported. In any case, the nub of that part of the State Department's case that rests on the data now made public, is that the concentrations now reported are greater than those found in grain that has been contaminated with Fusarium fungi in natural circumstances. The comparison seems to be generally accepted. Even allowing for the improved methods of analysis now available, it is unlikely that the samples recovered from South-East Asia have been contaminated by the natural growth of Fusarium species on the spot. But even this is not the clinching argument the United States State Department would like it to be.

The several objections to the use of these data will seem pettifogging to those who know what case they want to prove, but are nonetheless worth stating openly. First, four samples of such small bulk and of such different kinds are hardly enough to demonstrate the internal reproducibility of the results now arrived at. Worse still, those responsible for the chemical analysis have no knowledge of how the samples they have dealt with were collected, stored and transported. Indeed, they can have no way of being sure that the mycotoxins whose presence they have demonstrated were not added to the samples by some agency or individual anxious that the State Department should have a persuasive tale to tell. This dark suspicion, which nay seem unjust to a responsible government such as that of the United States, cannot unfortunately be shaken off, for the intelligence community responsible for collecting the samples has a shaky

reputation for veracity. The only solution to this dilemma is, of course, that those responsible should acknowledge that this potentially objective part of their case will be convincing only when there is much more material for analysis whose authenticity can be demonstrated.

For the time being, the analytical evidence falls far short of being compelling, at least within the professional community. The point can be simply put by means of the conventions of the scientific literature. Thus the State Department has agreed that Dr Mirocha and his colleagues may, if they wish, publish the results of their analyses in the scientific literature. (So, of course, they should do.) The abstract of an acceptable contribution to the literature along these lines might take the form:

We have analysed four samples of materials supplied by the State Department and have obtained the following results. . .

Referees would no doubt say that such a report was technically beyond reproach but of somewhat limited interest. But if the proposed publication has an abstract beginning:

We have analysed samples collected from four sites in South-East Asia soon after the use of chemical weapons... and have concluded that the Vietnamese have been using toxic agents derived from Fusarium species....

the referees would be down on them like a ton of bricks. This does not imply that the State Department's case falls down but rather that even with the apparently objective evidence for it now adduced, the case remains largely circumstantial.

The State Department has not yet proved its case, but it has raised a question that cannot be ignored. It is in everybody's interest that it should be answered, and quickly. One of the most chilling passages in the State Department's report is the speculation — it is no more — that mycotoxins rather than more lethal agents have been used in South-East Asia because they lead to bizarre forms of death calculated to frighten away the survivors of attacks. (Certainly the refugee camps of Thailand have been full for months.) If indeed it has now been shown that chemical weapons like these do have some military value, the outlook is awesome not merely for the luckless people of Laos and Kampuchea but for the rest of us. The prospect that it might be possible to reach an agreement between the major military powers to outlaw the use of chemical weapons in future wars, and to abandon their manufacture, will clearly be diminished if some group of generals has it firmly in its collective head that such a treaty would be a military loss.

So what should be done? The United Nations group of experts should clearly be asked — and helped — to complete the study on which it has embarked. The practical need is that it should be able to make a more detailed investigation of the regions in South-East Asia in which mycotoxins are said to have been used. The Soviet Union, which has some influence with the government of Vietnam, should recognize that its own case — that the allegations are a pack of lies — could only be strengthened by an investigation on the spot. And the United States should understand that the glee with which it has accused the Soviets of complicity in whatever has been happening in South-East Asia is counterproductive. Thus it serves no purpose but to confuse, that the State Department's report says that techniques for manufacturing and spraying trichothecenes from the air have been developed in the Soviet Union without adding that the objective (fully described in the literature) has been to control the spread of fungi other than Fusarium and related genera in forests. One of the materials, the trichothecene T-2, has even been canvassed as a rodenticide. (Nobody suggests that it would make sense to think of killing rats by spraying such a material from the air.)

What the State Department has not appreciated is that the question which it has legitimately asked will be regarded less seriously by those who alone can provide an objective answer if the statement of the problem is biased. The danger that the appearance of the State Department's document will be mistaken for a political ploy is in any case enhanced because the United States government is in the thick of persuading Congress to embark on the manufacture of binary chemical weapons in the

form of the 155 mm artillery shell known as M687, rightly castigated last week by Dr Matthew Meselson of Harvard University (before a Senate subcommittee) as militarily pointless and politically inflammatory. At the same time, to be fair, President Reagan has asked that the United States delegation to the Committee on Disarmament in Geneva reopen discussions on measures to control chemical weapons. The zeal with which those talks are prosecuted will be a powerful determinant of people's willingness to answer the State Department's question.

Professional propaganda

By what means should professional people, not only scientists, aim to influence public opinion?

The professions have often been accused of indifference to the problems of the societies in which they are embodied, and there is substance in the charge. Now, when many industrialized states are faced with unfamiliar and serious economic crises, governments may often rightly grumble that academics are more concerned with their own skins than with the solution of the economic problems about them. Other professions are similarly indictable. During the housing boom of the 1960s, for example, architects built dwellings without recognizing that people might not want to live in them, while teachers have for decades taught in schools without paying sufficient attention to the fitness of the curriculum for their students' needs. Not all, however, is disappointment. In many places, the legal professions have taken the lead in linking the practice of the law more closely with social realities and needs, while physicians have done much to change people's attitudes towards health and disease. So is it not entirely to be welcomed that there has recently been a rash of professional groups taking a special interest in what may be the most serious of

all contemporary social problems — the dangers of nuclear war? The short answer, which is "no", appears to offend some of those concerned (see page 386). That professional people have a responsibility to contribute their special knowledge to the solution of general problems is not in dispute, but only the means by which they do so. Similarly, there is no question that when a profession is, broadly speaking, agreed about the social consequences of some circumstance lying largely within its field, it should declare itself. It would thus be shocking if physicians were silent about the probable consequences of smoking. Unfortunately, however, the dangers of nuclear war do not lie exclusively within the province of a single profession, while there can be very few professions that are in broad agreement within themselves about the steps be taken to head off the danger.

This is why the emergence of groups of architects, or teachers, or even scientists, with catchy acronymic titles "against nuclear war", is a misfortune. By suggesting that the whole of a profession is in some way united about what should be done, these groups give the general public a false impression. By being separate from the more broadly based groups of people with the same aims, they run the risk of over-simplifying important problems. Medical groups, for example, may fairly make fun of official plans for civil defence against nuclear attack, but it would be more constructive if they did so in the context of the appalling difficulties, political and otherwise, of avoiding dependence on nuclear weapons.

In Britain and elsewhere in Western Europe, the immediate question is not whether nuclear war would be devastating—everybody is agreed on that—but whether individual governments should to some degree opt out of present arrangements for the defence of Europe. Another question is the basis on which arms control agreements might be negotiated. Professional groups usually profess no opinion on such practical questions, preferring to stay within the confines of their professional competence. The result is that, by what they say, they influence general opinion irrationally or at least subliminally. This is why they are open to the charge of deceit.

Industry funds in universities

New guidelines emerge from Pajaro Dunes

Washington

Universities should only accept research funds from private companies if secrecy is kept to the absolute minimum necessary for patent protection. At the same time, companies which fund such research should normally be entitled to receive exclusive licences on any useful results that emerge, at least for a period sufficient to prevent rival companies from unfairly exploiting the same research.

These were two of the principal conclusions to emerge from a three-day meeting between the presidents and selected faculty members of five top US research universities, and senior executive officers of ten leading biotechnology companies, held at the California coastal resort Pajaro Dunes at the end of last week.

The conference had been organized largely at the suggestion of Dr Donald Kennedy, president of Stanford University. Its main purpose was to discuss a range of controversial issues that have emerged over the past few years as universities have looked to industry as an alternative source of research support from the federal government and have increased their efforts to push research results into the market-place. Companies in turn have been turning their attention to the frontiers of biomedical research in their quest for new and improved products and industrial processes.

Others attending the conference included the presidents of Harvard, Massachusetts Institute of Technology, University of California and California Institute of Technology. Each had been asked to invite one university administrator, two faculty members with direct or indirect experience of dealing with outside companies, and two senior executives from companies with experience of sponsoring university research. The companies represented at the meeting ncluded Beckman Instruments, Syntex, Cetus Corporation, Applied Biosystems nc., Gillette Corporation, Eli Lilly, DuPont and Genentech.

Dr Kennedy stressed after the meeting hat the purpose had not been to agree on igid rules that should apply to each inversity, but rather to work out what he lescribed as a "framework for future elationships between universities and industry". Faculty members at several of he universities represented at Pajaro Dunes had already indicated their concern hat it should be left to each university to

decide how broad principles should be interpreted into policy — a policy that last week's meeting was quick to endorse.

Nevertheless, criticism that the conference had been limited to senior administrators and scientists on both sides was expressed in a letter to the participants signed by 25 scientists at research universities across the country, as well as several prominent union and consumer spokesmen such as Anthony Mazzochi of the Oil Chemical and Atomic Workers, and Ralph Nader.

The letter invited the participants to attend a second conference later this summer, at which the same topics will be discussed but primarily from the point of view of groups both within and outside universities which felt they had been unfairly excluded from last week's meeting. The letter quoted from the final speech delivered by President Eisenhower, in which he criticized not only the growing power of the "military-industrial complex" but also the danger that important policy issues were increasingly

being decided by a scientific and technical elite, rather than through open democratic processes.

Dr Kennedy has already agreed to take part in this second conference. He also said on Saturday that he would help the organizers of the conference to raise the necessary funds.

The Pajaro Dunes meeting produced agreement on an 11-page statement which set out some principles as a basis from which individual universities can develop guidelines and codes of conduct. The statement stressed, for example, that although links should be encouraged between faculty members and outside companies since these were considered mutually beneficial, "professional relationships with commercial firms should not be allowed to interfere with responsibilities for teaching and research"

The statement also said that in general it was not appropriate for universities to own substantial equity in companies which were staffed by their own faculty members. This is a sensitive point at Harvard, which

Flying start towards French law

The proposed French "research law", on which many of the plans of the minister for research and technology, Jean-Pierre Chevènement, depend, has cleared its first hurdle with a flying leap. The Economic and Social Council — a kind of litmus paper of the French nation — was not satisfied with giving mere approval to the law last week. Rather, it rearranged and added sentences to the draft bill to stress the significance of the new plans for France, indicating that they must be considered to be political priorities.

This is no slight thing, as the finance minister, Jacques Delors, recently put all spending ministries (including Chevènement's) on a tight rein. Something like a quarter of the new money offered to laboratories by Chevènement has had to be frozen, despite the minister's strong opposition. But, says the Economic and Social Council, "expenditure on research and development must escape, so far as is possible, from the present economic difficulties".

Money was not the only thing the council had in mind. Its members considered that the links between research and education need to be tightened; and so the council added phrases to the law which imply that Chevènement and the minister for national education, M. Alain Savary, must get together quickly to work something out, before Savary presents his own law to parliament in the autumn.

The council also stressed regionalization, sharpening the definition of the proposed "regional consultative committees" on research and technology. It suggested words guaranteeing the mobility of personnel, and, in particular, emphasized the use of the French language in science. The use of French is "a fundamental objective" said the council, but admitted that it would be difficult to achieve. The research law should define a precise strategy, and the ministry should keep the council informed of progress on this issue, the council requested.

The broad support of the council for the research law will be welcome and significant, because the council is an important — if unusual — constitutional body. Its 200 members are drawn from all walks of life, but particularly from the working classes (as 140 members are supported by trades unions); and it gives its opinion and advice on such matters as are referred to it by the prime minister, or on matters that it chooses to study on its own behalf. Its advice is usually taken before major bills are put before the National Assembly, and although the advice is not binding, it would be politically inept to ignore it. Moreover, since the unions are strongly represented on the council, and since the same unions have a strong influence on the present socialist government, the council might be thought to have more weight than it had in the past.

The next ports of call for the draft law will be the Council of State (to check legality), the Council of Ministers (for final political approval by the government), and ultimately — perhaps by early summer — the National Assembly for parliamentary debate, and, if successful, passage into law.

Robert Walgate

eighteen months ago backed away in the face of a flood of national publicity from a proposal that it should share the equity in a company being set up by members of its department of biology.

Both university and industry representatives agreed that research agreements should require the minimum amount of secrecy, and that in general university scientists working with industry funds should retain full rights of disclosure on their research results.

One controversial topic which was discussed at the meeting was how to avoid potential conflicts of interest when a university scientist is involved with both university and private research teams working in closely related fields. The participants agreed that universities should be encouraged to draw up explicit conflictof-interest rules, and also that any research agreements with private companies should not "impair the education of students, interfere with the choice by faculty members of the scientific questions or line of inquiry they pursue, or divert the energies of faculty members from their primary obligations of teaching and research".

There was apparently more disagreement on whether it was appropriate to grant companies which sponsor university research an exclusive right to use the results of that research. Some participants argued that this was going too far, and that although the company should be offered a royalty-free licence, the patent should also be offered to others at the same time. Some argued, however, that non-exclusive licences would discourage companies from developing a new product, and that an exclusive licence to the results was an appropriate quid pro quo for research support. If exclusive licences were not permitted, companies might be reluctant to support university research, said President Derek Bok of Harvard University.

The meeting had been described as "Asilomar II", a reference to the 1975 meeting on the safety of recombinant DNA research which took place a few miles away from Pajaro Dunes. Just as the earlier meeting had provided the basis for the subsequent development of the safety guidelines on DNA research, Dr Kennedy said after last week's meeting that it had marked the beginning of an attempt to establish a national consensus on guidelines for collaboration between universities and industry.

News of the new guidelines, however, is likely to evoke just as much controversy as the original Asilomar document. Graduate students at Stanford have already organized a series of meetings to discuss their perspective on the impact of the new university/industry links (Nature 25 March, p. 283). The Pajaro Dunes meeting had defined the arena in which future debates between supporters and critics of close university/industry links will inevitably take place.

David Dickson

Polish science

Travelling again

A few Polish scientists are now arriving in Western laboratories and universities to take up exchange places arranged before the imposition of martial law. The delay in their arrival has not been due simply to the general confusion following the army takeover; they bring with them news of emergency regulations for scientific trips, which demand, in particular, that any such trip must be "closely in line with the aims of the foreign policy of the Polish People's Republic and the socio-economic and scientific policy of the country".

Under these emergency regulations, any proposed trip must be submitted for detailed analysis by the director of the institute or rector of the university where the applicant works. This has to take into account not merely the scientific purpose and the cost-effectiveness of the trip (especially as regards foreign currency), but also whether or not the applicant can be guaranteed "to represent the political interests of the Polish People's Republic". In particular, trips will not be authorized for persons "who have actively worked to the detriment of the state, or who have broken the regulations of the decree on martial law". (This clause, if strictly applied, would exclude scientists working in several institutes of the Academy of Sciences, the Swierk nuclear research institute, and other academic establishments which responded to the imposition of martial law by protest strikes.) Relatives of scientists already working abroad will not be permitted to join them, although it is not made clear whether this is simply due to the shortage of currency, or whether it is intended as a means of ensuring that the scientists concerned will return at the end of their tour of duty.

Preferential treatment, it seems, will be given to long-term exchanges, especially if they are concerned with research into subjects of particular significance for the Polish economy, and if the proposed visit is to a "leading" scientific institution abroad where the scientific and practical reward is self-evident. Visits planned under existing exchange agreements and contracts for visiting lecturers will also be given a more favoured status, while the officials of international scientific societies, and academics invited to take the chair at international congresses and symposia (if not otherwise disqualified) should be enabled to travel "in order to facilitate the participation of Polish scientists in leading international scientific events".

Students, on the other hand, are to have their applications "delayed", except for students studying at universities in socialist countries on the basis of international agreements, and students sent abroad by the Ministry of Science, Higher Education and Technology for one- or two-semester "short courses". The same delaying process is to be applied to researchers wishing to go abroad to collect archive material, consult with their colleagues on "non-priority" matters, or to take a "passive part" in an international conference.

Vera Rich

Universities in industry

Imperial goals

Imperial College in the University of London has set up a manufacturing company with venture capital. The college, which is providing the facilities for the new company, will share the equity equally with Technical Development Capital Ltd (TDC), a subsidiary of the Finance for Industry Group, which is putting up £400,000 as initial investment. Imperial Biotechnology Ltd, as the new company is called, will use the college's pilot fermentation plant to manufacture purified enzymes, proteins and specialized fermentation products. These will be used for the chemical and mainly pharmaceutical industries.

The new company is primarily intended to provide a solution to the college's recent difficulties in funding the fermentation plant, which is housed in the biochemistry department. Although the plant had been earning contract money, the college could no longer make up the running costs out of central funds. It is hoped that the new company will be at least self-financing, eventually achieving a turnover of a few million pounds per year.

About twenty staff working with the fermentation plant will be transferred from the college payroll to that of the new company. They will retain their existing commitments to teaching and research. Management of the plant, however, will be transferred from Professor Brian Hartley, head of the biochemistry department, to a new management team appointed by TDC. Dr Trevor Langley, formerly with Whatman Biochemicals Ltd., has been made managing director of Imperial Biotechnology Ltd.

Professor Hartley, a critic of the government's unwillingness to support more biotechnology posts in British universities, plans to use some of the money released by transferring staff to the company payroll to establish two new academic posts in the Centre for Biotechnology which he is at present establishing.

Imperial Biotechnology Ltd will operate much as any other company, using profits to finance expansion. It will, however, benefit from its position on the college campus by maintaining close links with research. Professor Hartley, who has links with the Swiss company Biogen, will also be scientific adviser to the new company. He sees no conflict of interest.

Judy Redfearn

Biotechnology

Looking ahead

Bethesda Research Laboratories (BRL), the Maryland company that shook the US biotechnology industry by announcing that cash-flow problems had made it necessary to make redundant more than a third of its 450 staff, seems — at least temporarily — to be out of the woods.

Company officials are confidently predicting that, despite the setback to its expansion plans, BRL will double this year the \$10 million sales which it achieved in 1981, thus maintaining the pattern of geometrical growth that the company has managed since its foundation in 1976. Comparable sales increases are being talked about for 1983 and 1984. Private investors in BRL have endorsed the line being pushed by Mr Stephen Turner, BRL's founder and president, that "leaner is fitter" - the argument, ironically, that is being used by President Reagan's science adviser, Dr Jay Keyworth, to justify cuts in federal support for research and development.

The company has just announced that it has been able to raise an extra \$5 million from its original investors, many of whom are based in Europe. According to Mr Turner, this should be enough to provide a stable base for a steady expansion of its product range, originally focused on restriction enzymes but subsequently expanded to include other biological

products such as monoclonal antibodies as well as diagnostic screening kits and a nucleic acid analyser.

Mr Turner blames the company's recent difficulties on the rapid drying up of venture capital in the United States in the past six months. Last year, anticipating that it would have little difficulty in raising an anticipated \$40 million through a public stock offering, the company laid the groundwork for an ambitious expansion programme, dividing its research products division into separate molecular biology and biological chemistry sections, and significantly increasing its research staff.

In recent months, however, a declining inflation rate and new tax incentives have taken some of the glamour out of venture capital dealings as an alternative to other, more traditional forms of investment. In addition, much of the available venture capital is said to have been soaked up by some of the early public offerings — such as that launched by Cetus a year ago, which managed to raise over \$100 million in the largest new issue ever experienced by Wall Street.

As a result, many of the small biotechnology companies launched in the past two or three years are experiencing severe difficulties in raising the capital they need to keep going, a situation that Mr Turner believes could last for at least another year. Several industry analysts expect that up to one half of the companies could disappear within the next few years, some being absorbed into larger

Rorvik versus Bromhall

Washington

Hailed in 1978 on the book jacket as "the scientific breakthrough of the century", David Rorvik's book In His Image: The cloning of a Human was declared by a Philadelphia judge the same year to be "a hoax and a fraud". Rorvik returns to a Philadelphia court next week when Dr Derek Bromhall from the University of Oxford, who claims that his research was misused, will sue for damages against Rorvik and his publisher Lippincott and Co. (now owned by Harper and Row).

Mr Allan Friedman, Bromhall's lawyer and an associate of the firm Raynes, McCarty, Binder and Mundy, claims that Lippincott showed "reckless disregard for publishing ethics". He says that his client's case turns on two issues. The first is the claim that Rorvik invaded Dr Bromhall's privacy by quoting his cloning techniques in the text and by mentioning his name in the book's footnotes as a "personal communication" without approval. The second claim is that Mr Rorvik fraudulently acquired an abstract of Dr Bromhall's doctoral thesis by representing himself as a scientific researcher preparing a project on mammalian cloning.

Mr Rorvik's attorney, Samuel Klein of Kohn, Savett, Marian and Graf, claims that Bromhall's information did not include "novel and unique" concepts, that the thesis was already on microfilm and that a summary had already appeared in the scientific literature (*Nature* 258, 719; 1975). Furthermore, he adds, there has never been disagreement over the fact that all references to Bromhall's work were fully accurate.

Mr Klein also plans to argue that in the single letter written by Mr Rorvik to Dr Bromhall, his client identified himself as a freelance journalist and that Dr Bromhall's presentation of his nine-page abstract was unsolicited. There was no oral communication between Rorvik and Bromhall at the time of this correspondence.

The trial promises to become heated, for neither party plans to settle out of court. Mr Klein also says he will question Dr Bromhall's wish to keep his distance from the book in light of the fact that Dr Bromhall "voluntarily associated himself" with the film Boys of Brazil, which portrayed the cloning of multiple Hitlers. But Friedman says that Bromhall's voluntary association with a film presented as fiction is very different from an involuntary association with a book whose author claimed it to be non-fiction.

The trial is expected to last several weeks and many scientists will make appearances for both sides.

Michael D. Stein

corporations, others filing for bankruptcy or actively seeking mergers. BRL claims to be in a stronger situation than some of the other companies since it is already selling products on the market.

"The days of over-expectation and pure speculation are behind us and the time has come to fine-tune operations and get down to the business of running a business," says Mr Turner. "That's what we have done at BRL."

Similar sentiments are expressed by Frederick R. Adler, a New York lawyer who has helped to set up a number of high technology companies in the computer field, and who has recently been appointed to BRL's board of directors. "The computer industry taught us that business can successfully serve science. We're now translating that lesson to biotechnology", he says.

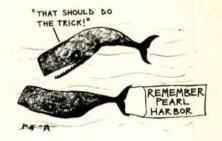

David Dickson

Sperm whale catch limits

No decision

A head-on clash between conservationist countries and Japan, the main whaling nation, was averted on Thursday when a special meeting in the United Kingdom of the International Whaling Commission (IWC) agreed to defer a decision on sperm whale catch limits until the annual general meeting in July. The conservationist countries abandoned their attempt to impose a total ban on sperm whaling after the scientific committee failed to produce a conclusive report.

Catch limits are usually set at the annual meeting of IWC. Last week's special meeting was convened because the scientific committee had not been able to offer unequivocal advice to the July 1981 meeting. Earlier this year, 32 scientists from 12 countries met in Cambridge to analyse sperm whale stocks. Computer tests were run using two rival models, one backed by the Japanese, the other developed by the International Institute of Environment and Development (IIED).

All except the Japanese scientists at last week's meeting supported the IIED model. However, the committee failed to offer any definite advice on catch limits. According to IWC criteria that stocks should be protected when they fall below ten per cent of maximum sustained yield (the maximum number of whales that can be harvested on an infinite basis without a decline in population), the IIED analysis indicated

that males should be totally protected, but a catch of 831 females could be permitted. But the analysis also indicated that even with a zero catch the stocks would continue to decline for several years. The biological reason for this is that sperm whales are polygynous so that the past removal of breeding males, favoured by the whalers because of their large size, has resulted in a decline in the pregnancy rate of the stock.

Therefore, the Japanese argue that their current quota of 890 would make little difference to the sperm whale population, particularly since the number of exploitable whales was estimated by the IIED team to be around 200,000. But conservationist countries are keen to see a zero quota, pointing to the predicted decline in population with no fishing at all.

The inability of the special meeting to come up with catch limits was not so much the result of scientific equivocation as a political move to produce a compromise. The conservationist countries feared that had they enforced a quota unacceptable to the whaling nations, Japan would have exercised its right to object and both the procedure for cooperation and the whole credibility of IWC would have been seriously damaged.

The annual meeting of IWC in July may be faced with pressure for a ban from the conservationist countries, which will be in the majority. If Japan refuses to compromise and registers an objection, the conservationists would then have to try to apply the ultimate sanction — a US ban on Japanese fishing in its waters.

Jane Wynn

Environmental law

Count the risks

Washington

A subcommittee of the House of Representatives has taken a first step towards building scientific risk analysis into the federal government's regulations on environmental and safety hazards. A bill passed by a subcommittee of the Science and Technology Committee would establish a new programme under the White House's Office of Science and Technology Policy (OSTP) "to improve and facilitate" the use of risk analysis in regulatory decisions. The bill will now go to the full committee, whose chairman, Mr Don Fuqua of Florida, supports it.

The Reagan Administration is less welcoming, feeling that the goals of the proposed law could more simply be attained by rationalizing new and existing regulations. But according to OSTP, the Administration will probably find the bill "acceptable" as long as certain amendments are made.

Various members of the Administration argued in their testimony to the subcommittee that they have already taken steps to introduce a more "rational" approach to regulation. Last February, for example, President Reagan put out an executive order requiring all proposed new regulations to be accompanied by a costbenefit analysis demonstrating that they represented the most cost-effective way of reaching their declared goals. The White House has also announced that the Inter-

agency Regulatory Liaison Group, established under President Carter to coordinate actions by different agencies, would be reconstituted as a new committee under the chairmanship of the President's Science Advisor, Dr Jay Keyworth, with the task of improving the scientific basis of regulatory decision-making.

Such changes have not satisfied the members of the House committee. Thus the new bill would assign to OSTP the specific role of establishing a mechanism for coordinating the risk analysis programmes among the participating federal agencies, primarily the Consumer Product Safety Commission, the Food and Drug Administration, the Environmental Protection Agency and the Department of Labor's Occupational Safety and Health Administration. And the National Science Foundation would be required to draw up a programme of research to make the use of risk analysis more effective. In addition, the various federal agencies would each be required to undertake a "prototypical risk analysis study".

Various powerful lobby groups, representing for example the agricultural or the nuclear power industry, have long been pushing for revisions to regulatory decision-making along these lines. The bill is therefore unlikely to lack supporters if it is sent by the full committee to the floor of the House of Representatives. But it is also likely to generate substantial opposition. Many Democrats, particularly those with close links with the labour unions, see attempts to "rationalize" regulation as a smokescreen to legitimize less stringent health and safety controls.

The Administration is likely to stand aside from any such debates. Although it claims to have made significant progress behind the scenes in eliminating unnecessary or redundant regulations, it is becoming wary of taking highly-publicized actions that might be interpreted as "antiregulatory" given the apparent continued public support for strict environmental and health and safety controls — and the importance of the congressional elections later this year.

In a related effort to reduce the impact of federal regulations, the US Senate last week approved a proposed new bill which would give Congress the power to overturn regulations being proposed by any federal agency. The bill is being resisted by the Reagan Administration, which sees it as an attempt by Congress to place limits on the flexibility of the executive branch. It has also received strong opposition from environmental and labour groups, who argue that it would provide vast scope for individual companies and industries to lobby Congress to prevent certain regulations from coming into effect. Supporters of the new ruling, however, argue that regulatory agencies frequently exceed their congressional mandates, and that checks are now needed to limit their autonomy. **David Dickson**

Join the queue for monoclonals

St Louis

The Monsanto Corporation of St Louis, Missouri, has made a multimillion dollar agreement with nearby Washington University to produce monoclonal antibodies, the second such agreement the university has made with the chemical industry in the past six months.

Monsanto says it has agreed to put \$1.8 million into research projects at the university during the next three years. No contract has so far been signed between the university and Monsanto but the deal is expected to be similar to that made with Mallinckrodt Inc., also of St Louis. Last September, Mallinckrodt committed \$3.9 million to monoclonal antibody research at Washington University, the largest industry agreement ever made with an American university for this type of research.

Mallinckrodt's three-year commitment is a major one for the company, which is economizing in other areas. But despite uncertainties about patents, monoclonal antibodies hold out enormous commercial promise. Dr Thomas O. Oesterling, Mallinckrodt's

vice-president for research and development, says his company's primary interest is in *in vitro* diagnosis, where monoclonal antibodies allow much improved standardization in diagnostic kits, but it is looking at other uses. "A monoclonal antibody could carry an isotope for imaging to a target cell for *in vivo* diagnosis", and from there it is "a logical extension to therapy".

The contract between Mallinckrodt and Washington University provides for the university to hold the patents for useful products of the joint venture, but for Mallinckrodt to have the right to license them. The university's share of royalties is dependent on the success of the product on the market.

One aspect that is covered by the arrangement with Mallinckrodt is the right of publication. Individual investigators do not profit personally from an invention, although some of the royalties will be ploughed back into research in the individual's laboratory, but the individual does retain the right to publication, with the proviso that the company can screen for patentable material.

Karen Freeman

Making waves

Following hard on the heels of Amersham International, another "public" company — the Hydraulic Research Station at Wallingford, Oxfordshire — is to go "private" on 1 April, with Dr John Weare as managing director and chief executive.

All of the present staff will be seconded from the civil service to the company for one year, after which 80 per cent (about 200 people) are likely to be offered long-term contracts.

The transfer was not without its hitches. Staff at first resisted the move fearing that "privatization" would mean loss of government backing and lead to a lessening of the station's world-wide reputation. In fact, no drastic cutbacks are planned and the general feeling is that, freed from government constraints, the company will be better able to respond swiftly and competently to the needs of the civil engineering industry.

Sara Nash

Indian science education

Falling behind

New Delhi

In a major new exercise, Indian government circles concerned with science education are trying to find resources equivalent to \$55 million for the next three years to strengthen the science education base of the universities.

The government realizes that lack of support has allowed the university science system to run down and that this trend, if continued, may prove irreversible. The role of universities as advanced centres of teaching and research has been eroded by the rapid expansion in the number of institutions and students without a corresponding increase in the necessary facilities.

The Science Advisory Committee to the Cabinet (SACC) has long felt that the resources of the universities should be augmented as this would not only benefit universities but also assist the major scientific agencies of the country and industrial enterprises. The scientific manpower requirements of these agencies will be met by the universities. SACC recommended that central and state governments and industrial companies should combine to contribute about \$55 million to strengthen the science base of the universities. A detailed scheme is expected to be submitted to the cabinet for approval.

The Indian government also feels that the current pressure on the universities in terms of the enormous intake of science students should be reduced, and that equal opportunities should be provided for gainful employment for those who do not pursue careers in science after passing the school level examination. This system will

then provide the smaller number of science students with proper facilities. And as lack of instrumentation is a serious handicap for research in universities, the government is now considering stepping up instrument production.

It is widely believed also that the links of university research and national scientific agencies with public sector enterprises need to be strengthened. The present barriers between the two are impending the country's scientific and technological progress.

Sunil Saraf

•Speaking at the invitation of the Science Policy Foundation in London last week, Mrs Indira Gandhi reasserted her commitment to the strengthening of Indian science and technology. Without internal strength, she said, the governments of developing nations cannot withstand the tendency of some nations to use the transfer of technology as an instrument of foreign aid. "We have not got out of one empire to get into another" was her reply when later questioned as to her country's relationship with the transnational corporations.

Self-reliance is also necessary, Mrs Gandhi said, because the problems of India are increasingly different from those of the developed nations. India needs to curb population growth, to find ways to grow crops in soil of low moisture and to prevent cholera and tuberculosis, not cancer and heart disease.

At the same time it is of immense benefit, even a necessity, for India to continue its own atomic energy, oceanographic and space programmes. "Our space effort is important for education and communication and deeper knowledge of the monsoon, which rules our economic calendar."

While emphasizing the unacknowledged, reverse economic aid donated by emigré Indians to "Western" scientific progress, Mrs Gandhi said that opportunities for intellectually challenging work must be increased to keep talented Indian scientists in the services of their own people

Peter Newmark

National Research Council

Changes ahead

Washington

The US National Academy of Sciences is carrying out a major reshuffle of the complex organizational structure of its National Research Council (NRC). The purpose, according the academy's new president, Dr Frank Press, is "to meet the opportunities ahead of us, to promote greater efficiency in our ability to respond to governmental requests and to meet changing economic circumstances".

NRC, the operational arm of the academy, provides advice to and carries out research on a contract basis for the federal government and other

organizations. Since 1973, it has operated through four assemblies — each based on a single discipline or set of disciplines — and four multidisciplinary commissions.

This arrangement was introduced to improve NRC's ability to tackle policy questions that frequently cross disciplinary boundaries. In practice, however, there has frequently been confusion over the relative responsibilities of the various assemblies and commissions — a situation which Dr Press hopes the new structure will avoid.

Three of the assemblies will therefore be merged with three of the commissions. The Assembly of Behavioral and Social Sciences will be merged with the Commission on Human Resources to become the Commission on Behavioral, Social Sciences and Education; the Assembly of Engineering will merge with the Commission on Sociotechnical Systems to become the Commission on Engineering and Social Systems; and the Assembly on Mathematical and Physical Sciences will join with the Commission on Natural Resources to become the Commission on Physical Sciences and Resources.

The future of the fourth assembly, the Assembly of Life Sciences, some of whose work currently overlaps with that of the Institute of Medicine, will be discussed at the next meeting of NRC's governing board which takes place on 3 April. Any changes to the constitution of the Institute of Medicine would have to be approved by its members.

The fourth commission, on international relations, will be transformed into a new Office of International Affairs, whose executive director will be Dr Victor Rabinowitch. The activities of the office will be overseen by a panel comprising the foreign secretary of the academy, Dr Walter Rosenblith, the foreign secretary of the National Academy of Engineering, the president of the Institute of Medicine, and Dr Rabinowitch; this panel will also undertake policy formulation for the whole of the academy complex.

The reorganization is part of a broad attempt by Dr Press to streamline the academy's activities and enable it to play a more active part in Washington science policy debates. One example of this new approach is a panel which is being set up under the Committee on Science and Public Policy (COSPUP) to examine the implications of the closer links being drawn between US universities and the Department of Defense.

The panel will examine a range of issues raised by this enhanced relationship, from the application of export controls to unclassified research to broader impacts on academic freedom. Funding for the study has already been promised by the Defense Department itself, the National Science Foundation and the American Association for the Advancement of Science; NAS is seeking additional funds from outside sources.

David Dickson

CORRESPONDENCE

The coal of today

Sir — The content of the leading article "A strategy for coal" (Nature 25 February, p.636) indicates a view based on out-dated knowledge of the coal industry. The economic arguments used ignore, for example, the fact that British coal is the most competitive in the European Community. The latest published coal production cost comparisons (for 1980) are:

	£ per to
Belgium	61
France	45
West Germany	44
UK (1980/81)	35

The article mentions the design of microcircuits as if this was a world apart from coal mining. In fact, Britain's technologically advanced coal industry extensively uses computers, microprocessors, transducers, lasers and other modern aids. There is obviously no future in the microtechnology unless there are industries like coal to use the products. The National Coal Board and private enterprise manufacturers have successfully designed and introduced computerized control and monitoring systems for colliery operations and these are creating considerable interest overseas.

Longwall mining technology was pioneered in Britain and equipment sales remain significant export earners — and have resulted in record-breaking colliery performances in the United States, South Africa and Australia. There are many other examples showing that our indigenous coal production is serving Britain well — and it will need to do so in the future. Incidentally, the Australian exports mentioned in the Nature article include a high proportion of opencast coal which is also profitably produced in Britain. ROBERT HUNT Dowty Group, Cheltenham, UK

Doves in false garb

SIR - Having read more than once your leading article of 18 February (p.542) under the condemnatory title above, I am still puzzled that you provide no evidence, by way of argument, to justify the statement "The claim by the anti-nuclear movement of professional support is mostly a sham". The occasion you were commenting upon, the Conference of Professions for World Disarmament and Development, convened under the auspices of the World Disarmament Campaign, made no claim to speak officially for the major professional societies. But the attendance of several hundred professional people, and the rapid growth of specialist bodies such as Scientists Against Nuclear Arms (SANA), Medical Campaign Against Nuclear Weapons, and Teachers for Peace suggests that there are many who do agree in general terms that "the professions as such have a responsibility to alert the general public to the great issues that confront society". You seek to deny this, yet you accept in the very next sentence that "there is a sense in which professional people, acting individually, may be held to shoulder an extra responsibility for giving wider currency to their conclusions about important issues on which they have some special knowledge".

Why the emphasis on acting individually?

Why do you consider it "not respectable" for scientists of different disciplines to come together through SANA to pool their varied expertise relevant to the effects of nuclear war on Britain, and then to make known their conclusions based on this special knowledge? Why try to belittle the work of the Medical Campaign Against Nuclear Weapons and the Medical Association for the Prevention of War, who point out to their colleagues that nuclear war would be a medical catastrophe beyond reach of any cure, so that it becomes a professional duty to seek its prevention?

You complain that the major professional bodies "are needlessly indifferent to important public issues well within the spheres in which their professional competence could command respect". Yet you condemn, by implication, the work of the British Medical Association to study the medical effects of nuclear war, and the efforts within the teaching profession to direct attention to the role that education plays in forming public attitudes to other countries and to conflicts within and between countries. Do you not accept, for your own profession of journalism, some responsibility for the way in which the press and television treat major issues such as nuclear war and thus influence the formation of public opinions?

CHRISTOPHER MEREDITH
(Secretary, Scientists Against
Milton Keynes, UK Nuclear Arms)

SIR — The leading article on the meeting of professional groups concerned with supporting nuclear disarmament makes a number of astonishing assertions (*Nature* 18 February, p.542). For instance it seems to question the right of the medical profession to express an opinion on the issue, claiming that "Physicians have been consistently indifferent to the quality of health care (in Britain)". This suggestion is as insulting to the medical profession as it is unfounded.

The health care professions should and do have a special knowledge of the medical effects of nuclear weapons as have other professional bodies, such as architects, specialized knowledge of such matters as affect their sphere. It would seem entirely understandable, and we would submit entirely proper, that such organizations should undertake to publicize as widely as possible the full effects of the use of nuclear weapons.

The rapidly expanding Medical Campaign Against Nuclear Weapons, and no doubt the other professional groups represented at the meeting discussed in the article, reflect the widespread concern over the proliferation of nuclear weapons and the apparent increasing risk of their use. In the United States, professional bodies voice similar concerns. Thus a recent report of the American Medical Association stated "There is no adequate medical response to a nuclear holocaust".

Doctors and other professional organizations not only have a right but a duty to speak out on the subject of nuclear weapons and nuclear warfare. They do so in order to bring the facts to the attention of their colleagues, politicians and the general public and not, in the remarkable words of the leader, to capture any "mediaeval mystique".

M. HARTOG, J.H. BAUMER, P.J. FLEMING, M.J. HALL

University of Bristol, UK

SIR — The views expressed in your leading article entitled "Doves in false garb" (*Nature* 18 February, p.542) were put forward provocatively enough to require reply.

You have allowed that "there is a sense in which professional people, acting individually, may be held to shoulder an extra responsibility for giving wider currency to their conclusions about important issues on which they have some special knowledge". Why must they be "acting individually"? Why, that is, when medical people act together, do you decry this as their "attempt to invest their legitimate causes with spurious authority . . . a deceit"?

Medical people certainly have no entitlement to speak with any lofty authority. But we have seen people die of burns and crush injuries, and have had to repair terrible lacerations. There is always at such times the question "why need this have happened?". and physicians, surgeons and general practitioners alike bear, or should bear, prevention constantly in mind. For epidemiology prevention is the raison d'être. It means searching for any predisposing causes of disease or injury and proclaiming them when they are found. For many of us it is no longer tenable to act in this way where, say, chemical carcinogenesis, dietary causes of disease or accidents in the home are concerned, but to remain mute on the dangers of nuclear detonations. Psychiatrists especially are left with few illusions about human fallibility. STEWART BRITTEN London, UK

A final word

SIR — "The creationists may have lost the battle in Arkansas but they are unlikely to abandon the war on which they are engaged" (Nature, 14 January, p.85).

Your journal has, for several months, lent itself as a battleground for this verbal brawl by continuing to publish letters from both sides, many of which do not (and cannot) contain any elements of scientific reasoning. This correspondence has degenerated into a discussion of the Bible as a source of artistic inspiration (A.J. Hollin, *Nature*, 18 February, p.548) and such fine points as the positioning of a comma in Luke's gospel (F.W. Cousins, *Nature*, 11 February, p.452). These authors clearly have a sense of the absurd.

Nature is a journal with a large and mixed audience which serves not only to publish important scientific findings, but also to inform scientists about political issues which are of particular interest to them. The Arkansas trial was clearly one such issue. That trial is now over, and scientists wishing to continue the discussion should now look to do so from a platform where they might be better able to inform and enlighten the general public. Does Dr Salthe (Nature, 11 February, p.452) really need to point out to a scientific readership the folly of the statement that "The scientific community does not consider origins of life a part of evolutionary theory"?

Serious discussion of mechanisms involved in evolution has a place in this journal.

Advocates of God and *Genesis* should air their views elsewhere.

An end to the search for new drugs?

M. Weatherall*

THE discovery of new drugs is taking longer and becoming less productive1-3. In the United Kingdom the average time between first publication (itself usually years rather than months after studies begin) and marketing increased from 6 years in 1965 to 10 years in 19784. In the United States the average time between filing an "Investigational New Drug" (IND) - in effect advising the authorities of an impending trial in man — and approval by the authorities of a drug for general use increased from about 3½ years in 1967 to 9 years in 19765. One British pharmaceutical company has found⁶ that between 1972 and 1978, the number of animals used in safety testing increased from 600 to 1,200 or more and that the number of man-days spent by trained staff on a single nonrodent study increased from 275 to 480 despite improved working methods which saved 85 man-days. Unpublished figures from the Wellcome Foundation show that the cost of studies necessary before clinical trial of a drug intended for long-term use in man rose between 1965 and 1979 by a factor of 3.2 for toxicology and 5.2 for pharmacokinetics, even after correction for inflation.

The money for this work has to be found somewhere. The more that is spent on bringing one drug into general use, the fewer the total number of drugs that can be studied and the more necessary it becomes to concentrate on common diseases where the prospects of a financial return are greatest. Drugs for rare diseases sometimes called "orphan" drugs - such as triethylene tetramine for Wilson's disease⁷ or L-5-hydroxytryptophan for myoclonus⁸, are not commercially viable and so must be prepared in a physician's laboratory and encapsulated in a hospital pharmacy7 if patients are not to be allowed to die.

It seems probable that financial pressures have already reduced the total research in the United Kingdom directed at finding new drugs. Cavalla⁹ lists nine companies which have closed their research and development groups, with redundancies or reorganization.

It can, of course, be argued that drugs are useless if not positively dangerous, and that the resources used in drug research would be much better spent on measures of more general benefit to the health of the community. There is a need to balance drug development against spending on

*Dr Miles Weatherall was Director of Establishment, Wellcome Research Laboratories, Beckenham, Kent until, 1979. Present address: Willows, Church Lane, Charlbury, Oxfordshire OX7 3PX, UK

community health, preventive medicine and relevant education. But as the funds come from different sources, striking a balance is necessarily difficult. Making drug development a government responsibility is not, however, an answer. A government concerned to live within its income from taxation would face the same problems as industry, and would perhaps be even more reluctant to undertake the risks of financial loss associated with speculative research, the problems of making orphan drugs available for uncommon but killing diseases and so on. Ultimately, health can be achieved and maintained only by work. The limit of health care is the amount of work which is put into it, and unless the work is unpaid, the limit is economic.

Meanwhile, until the balancing act is achieved and the public desire for medication¹⁰ abates, drugs will continue to be a major element in therapeutics and better drugs will be sought. No drug is without its hazards. The one prediction that can con-

evidence about the effects of drugs used by specialists in closely supervised patients. The effects may differ greatly when a drug is released for widespread and unregulated use. Information about the overall prescribing of drugs is of little help in assessing benefit, while the proportion of prescribed drugs actually consumed by patients is usually not known. The reporting of adverse reactions is patchy and biassed, and the fashion for expressing alarm about iatrogenic disease needs to be tempered by a careful appraisal of how the sufferers would have fared without the treatment.

In particular instances, thorough studies allow an assessment of risk. Thus immunosuppressive treatment, with azathioprine, chlorambucil or cyclophosphamide, is used to prevent rejection of transplanted kidneys. These treatments carry a 1.3% risk of tumour induction and 0.4% risk of mortality within the period of observation¹³. But this risk has been estimated only after ten years of study. It could not

Public demand for totally safe drugs has led to excessive, costly and misleading toxicity testing. Such testing drains the resources which have been available for discovering much needed new drugs. Better public understanding of the limitations of toxicity testing and the hazards of medication is sorely needed in order to improve the prospects for diseases still needing effective treatments.

fidently be made about any new drug is that it will have unwanted effects, and dangers if misused¹¹. Moreover, it is usually difficult to assess what contribution drugs have made to the reduction of ill health and prolongation of life, when sanitation and nutrition have improved at the same time. Yet in a variety of circumstances, drugs are unequivocally saving individual lives¹², as with the use of antibiotics in a wide range of acute infectious diseases, and of vaccines in the elimination of smallpox throughout the world and in the minimization of diphtheria and poliomyelitis in many countries. Replacement therapy prolongs life unequivocally: no one could seriously maintain that all diabetics could remain healthy without insulin. There is no doubt that some drugs are vitally necessary.

There is also no doubt that over a wide range of drugs, the evaluation of therapeutic benefit is extremely difficult. Difficulties arise when prolongation of life and easement of disability are the main expectations. Mortality statistics in more developed countries are good, but morbidity statistics are variable and, except for notifiable diseases, hard to come by. Clinical trials seldom extend over more than a year or so, and by their nature give

have been estimated when renal transplantation began. Had it been possible to know it, and had it been added to the operative risks and other hazards, would it have been a reason for not embarking on the procedure and would most of the people now living with transplanted kidneys have been allowed to succumb to their disease?

Drugs are tools which function by modifying the processes of life, and they cannot be labelled good or bad without considerable knowledge of the circumstances in which they are actually used. For many diseases, the drugs available now are clearly inadequate to restore health or even minimize discomfort and disability. Allergy, arthritis, cancer, cardiovascular disease, congenital abnormalities, psychiatric, neurological and a variety of tropical diseases all await effective treatments. There is a rapid growth in knowledge about the biochemical disorders and genetic background of many of these conditions, and either from such knowledge or by more empirical methods, new drugs continue to be found. But there is a drug lag in countries which have the most sophisticated regulatory arrangements14, and a virtual halt to the discovery of new drugs for poorer and less healthy nations 15

One reason for the decline in innovation may be the difficulty of devising suitable laboratory experiments for identifying drugs for the unconquered diseases. When a disease is due to a known infecting organism, compounds can be selected according to knowledge of the biochemistry of the organism, or empirically. Such compounds can be tested against the organism in vitro and in vivo, and the most effective selected for further study. The search may be long. but the route is clear. It has led to the whole range of chemotherapeutic drugs and antibiotics which have outstanding powers of saving human and animal lives. But this field is largely worked out, except for the tropical diseases. It will grow again in importance, as more drug-resistant organisms evolve. The resources for such discoveries are still an important part of the infrastructure of public health.

Drug searches

For diseases not known to be due to an infecting organism, some other clue is necessary to start the search for useful new drugs. When a particular substance is shown to be lacking, its replacement is indicated, as with L-dopa for Parkinson's disease16 and, earlier, in the various endocrine gland failures. New local hormones or mediators continue to be discovered, but it remains to be seen how extensive the practical therapeutic consequences will be of the great body of recent work on prostaglandins, leukotrienes and neuropeptides. There are advances to be made in neuropharmacology as the relationships between disorders of synaptic transmission and mental disease become understood. At present the field is confused and confusing, and hampered by the lack of reliable animal models for essentially human disorders. So, too, diseases involving some ill-defined immunological disorder rheumatoid arthritis^{17,18}, allergies of all kinds, perhaps multiple sclerosis¹⁹ — must either await biochemical understanding or rely on animal models justified in the main because they give positive results with agents already known to be effective in the human disease. This is a route to me-too drugs (not necessarily worthless) and to much waste of resources on false positives, but it is not likely to lead to great innovations in therapy.

The other major strategy for discovering new drugs is to pursue the detail of a physiological or biochemical system and to exploit its practical application. This is the natural course of academic scientists, and has led to such important agents as insulin and dimercaprol. In the past thirty years, however, the practical application by academic scientists of their discoveries has declined²⁰, partly because the resources now needed for development are completely beyond the range of university facilities and partly because increasing specialization within universities has reduced the cross-links between approp-

riate specialists, especially organic chemists with pharmacologists, and pharmacologists with clinicians21. The fundamental approach has been pursued more successfully in industry, notably in Hitchings' work²² on purine and pyrimidine metabolism and inhibitory analogues, which led to drugs as diverse as the antimalarial pyrimethamine, the antineoplastic agent 6-mercaptopurine, the immunosuppressant azathioprine, allopurinol for gout and the antibacterial trimethoprim. More broadly, all the developments of drugs associated with neuroeffector and synaptic transmission rest on the fundamental work initiated by Dale at Wellcome Research Laboratories, extended in countless other institutes and applied to practical ends by many pharmaceutical manufacturers.

A major development of this kind is necessarily a long haul and involves extensive investment of resources in a concept, the therapeutic merit of which can be judged only at the end of the road. This kind of investment requires circumstances of prosperity and reasonable security, and is hindered if the always limited resources for research are frittered away in unimaginative and invalid routines.

In a reasonable world, the increasing difficulties of discovery and the seriousness of the incurable diseases may be seen as good grounds for a more tolerant attitude to the hazards of therapy. Desperate ills need desperate remedies, but the wish for completely safe remedies has had and is having the gravest effects on drug discovery²³. The problem of finding valid laboratory models for the unsuspected toxic effects of drugs is just as difficult as the problem of devising methods for detecting therapeutic potential.

The major tragedies which have created public alarm and fear and which have led to the condemnation of drugs have arisen in special circumstances (pregnancy and thalidomide; consumption of amine-rich foods and monoamine oxidase inhibitors: Japanese life and clioquinol24) or have been due to unexplained sensitivity in a minority of patients (triparanol25, practolol^{26,27}, clozapine^{28,29}). Practolol, a β -blocking agent introduced for the control of cardiac arrhythmias and subsequently found valuable also in hypertension, is particularly notable for the thoroughness with which its toxicology was studied in animals, to the satisfaction of registration authorities. Nevertheless, adverse reactions, some serious, developed in a small proportion of patients who received the drug; the ill-effects included skin rashes, impairment of secretions and, most gravely, corneal damage sometimes leading to impairment or loss of vision (the "oculomucocutaneous syndrome").

None of the recognized laboratory procedures gave warning of the serious clinical syndrome nor, even with hindsight, has a procedure been discoverd which would have predictive value. Other "idiosyncrasies" are associated with particular genetic factors, as with reactions to suxamethonium³⁰, primaquine³¹, penicillamine³², sodium aurothiomalate¹⁸ and hydralazine³². When much more is known about individual biochemical variation and its genetic control, it may be possible to predict that particular drugs will be hazardous to particular individuals. But the animal models of orthodox toxicity testing give no basis for such subtle predictions.

The unsatisfactoriness of predicting adverse effects in humans from animal experiments has been well known for a long time³³⁻³⁶. Positive findings in animal experiments are also not always reliable evidence of harm to man. Usually, positive findings in experiments in animals are grounds for not giving a compound to human beings at all, but sometimes some toxic effect in animals is discovered after a drug is well established in clinical use. Furosemide, a well tolerated and valuable diuretic in man, causes severe liver necrosis in mice³⁷ because of a metabolite which is not formed to a serious extent in humans 38. The nucleoside 6-azauridine is tolerated for relatively long periods for cancer chemotherapy in man: in dogs, smaller doses than are acceptable in man produce potentially lethal bone marrow depression in 7-10 days39. Intramuscular injection of iron sorbitol causes sarcomas at the site of injection in rats and rabbits⁴⁰. The implication for human therapeutics appeared serious⁴¹; but the nonspecificity of the effect in laboratory rodents was recognized42 and, nearly 20 years after the original observation in rats, only eight published cases could be found of tumours after intramuscular iron injection; their variety did not suggest a common origin from the injected material⁴³.

Species specificity

Every species has its own metabolic pattern, and no two species are likely to metabolize a drug identically44. Small differences in the rate of conversion of drug to inactive, or to toxic, metabolite can have large effects on the concentration of active substance at the point of action. Most experiments to seek toxic effects in whole animals involve oral administration: differences in diet, gut physiology, rate of passage and liver enzymes raise serious questions about the relevance of findings in rats or mice to man. Compounds which are not absorbed in laboratory animals are not, with minor exceptions, ever tested in man. Nobody knows how many drugs, which would be useful in man, have been lost in this way. Similarly compounds toxic in laboratory animals at doses near the predicted therapeutic level do not receive trial in man, so it is never revealed whether they would actually have been harmful in man. Thus we lack the evidence of the false positive element in animal toxicology studies39, so it is easy to give more weight to such studies than is justifiable.

The procedures45 which became

established after thalidomide whereby large numbers of animals were fed large amounts of drug for a long time, have become ritual "routine tests of limited value and governed by regulations rather than by rational thought". Reports on the results are submitted to regulatory bodies in confidence and seldom published. The experiments are rarely repeated by independent workers: nobody is motivated to find the very considerable resources needed to do so.

Supplementary tests — for effects in pregnancy and on fertility, for carcinogenicity, for mutagenicity - grow in number but not in validity, and the search for quicker and cheaper tests, notably using mutagenicity in bacteria in vitro as evidence of carcinogenicity in vivo, has added to the obstacles, uncertainties and expense of developing drugs. As with the primary toxicity tests, positive findings are a bar to further progress, and to validating the test, so that the procedures acquire a possibly unmerited aura of respectability. The greater the number of tests, the greater the chance of a false positive and the loss of a useful drug.

There are good reasons for special caution in applying results of experiments in vitro to conditions of practical use, especially when massive concentrations are used. In mutagenicity tests, for example, considerable adjustment of experimental conditions appears to be necessary to obtain a positive result with a chosen compound. Ashby and Styles⁴⁷ list 14 factors which can be varied in, and influence the outcome of, the Ames test, which is widely accepted as a standard basic procedure. By variation of any one or more of these factors, the sensitivity of the test can be altered, sometimes by as much as 400-fold. For the innocent who wish only for a black or white answer, the outcome can be readily changed from positive to negative or vice versa.

In vitro reliability

In other words, there is a considerable scope for adjusting the test to give the required answer with any specified compound, and it is a great help in selecting test conditions to know what answer is wanted. Ames and Hooper⁴⁸ observe that "using rat liver homogenate as a model for a rat's metabolism of foreign chemicals is a reasonable first approximation". But, in vivo, compounds are metabolized and excreted, either unchanged or as metabolites. It is as important to mimic the mechanisms of inactivation as of activation if misleading results are to be avoided. The actual concentrations to which DNA is exposed in real life are quite unpredictable from concentrations produced in such experiments in vitro. The use of human instead of rat liver would add marginally to the predictive value of such bacterial tests for human mutagenesis. The addition of further enzyme systems might be better still, but would not overcome the problem of relating the tests to real life concentrations and duration of exposure.

Indeed, unless mutagenicity in vivo differs from all known pharmacological effects, it will be affected by the concentration of the agent to which the DNA is exposed and by the length of time and by the frequency of exposure, none of which can be properly assessed from data in bacteria in vitro. Even if mammalian DNA is damaged in the same way as the DNA of bacteria in a test situation, repair mechanisms are well known in mammals49. and may annul any damage so caused. The extent of their protective role has yet to be established. But no compound has been proved to be a mutagen in man and, 35 years after the massive radiation of the people of Hiroshima and Nagasaki, no deleterious heritable mutations have been recognized, so the protection afforded by repair mechanisms has had a substantial trial and appears to be pretty good.

Finally "the" correlation between mutagenicity (in bacterial tests) and carcinogenicity in humans is anything but simple. Many more carcinogens are known in rats than in humans and demonstration of carcinogenesis in rats sometimes depends on notably large and repeated doses of the substance under test⁵⁰. The importance of a carcinogen, as of any other toxic or therapeutic agent, depends on the concentration and persistence of the substance at the site of action, or more roughly on the dose and duration of exposure. Disregard of quantitative considerations is the first step — and it can be a very long step indeed — towards nonsensical prediction and the abandonment of useful substances on ridiculous grounds50

The problem remains of deciding what weight to attach to results of ominous but uncertain significance. The quicker and cheaper a test, the greater the number of substances on which suspicion may be cast. The list already includes the essential antimalarial drug chloroquine51, and such more familiar substances as caffeine52, tap water⁵³ and oxygen⁵⁴. Common sense prevents alarm about oxygen, which does, after all, damage the lungs and central nervous system of adults⁵⁵ and cause blindness in premature infants56 at only five times the normally accepted concentration. Indentification of a hypothetical carcinogen or co-carcinogen among the solids dissolved in some samples of tap water is less certain to lead to a major advance in public health than to promote expensive but nugatory research, paid for by charity or the public purse.

Coffee drinkers are no more likely than smokers to be diverted from their habits. The epidemiological evidence of association between coffee drinking and carcinoma of the pancreas⁵⁷ requires further investigation to establish whether one causes the other or whether both arise from an unidentified cause, but such an investigation will at least relate directly to a human problem. Will regulatory

authorities become concerned with chloroquine regardless of its place in the control of malaria? The regulatory authorities mostly operate in the rich countries, which can afford them and which are relatively untroubled by malaria. If chloroquine were banned as a mutagen in any western country, would its further supply to less developed countries appear to be morally responsible? The difficulties of preventing "character assassination" of a drug are great, witness the problems of phenacetin⁵⁸, metronidazole⁵⁹⁻⁶¹ and Debendox⁶², but the resulting losses to human health may last for ever.

What really matters is what happens in everyday life. Recognition of the fallibility of laboratory studies has led to a welcome demand for surveillance of the effects of drugs in ordinary use23. However, it is very difficult to measure the incidence of adverse drug reactions^{63,64}, most of which are infrequent and occur in patients who are usually the recipients of several different drugs - and who may not necessarily consume the drugs prescribed for them. Naturally, a drug suspected of causing a reaction is withdrawn and many reactions subside. To give the suspected drug again so as to discover whether its toxic effect is reproducible, is hazardous and unethical, so evidence of individual cases is of very poor scientific quality.

Simplify regulation

Various schemes of surveillance have been proposed^{65,66}, by which it is hoped that quantity of evidence will overcome the weaknesses of separate observations. The accumulation of much data is essential. and the costs are substantial. If the price of drugs is not to rise, savings must be made elsewhere64. One obvious area is in preclinical evaluation and its administrative costs. The recent simplification in requirements in the United Kingdom for a clinical trial certificate⁶⁷ are therefore welcome, though the financial savings will be modest. Studies of post-marketing surveillance are desirable, but if expensive schemes add to the economic barriers of discovering new drugs, they may yet achieve more social loss than benefit.

A basic difficulty lies in public opinion, and in the public belief that drugs can be, and ought to be, completely safe. Public conception both of the probability and of the severity of a risk is complex and not well understood. A single large-scale tragedy evokes much fear, as after an air crash or the sudden revelation that many deformed babies had been born after the use of thalidomide, whereas a continuous series of small tragedies, as in road accidents, is treated apathetically^{68,69}. Most people understand that a surgical operation carries a finite risk, and face with more or less equanimity the remote possibility of death on the operating table or some other ill-fortune. But few appreciate a similar remote risk from consuming a drug, and the majority are correspondingly shocked

when such an event occurs. The public view might be expressed in such words as "everything that could have been done to make a drug safe should have been done; even if tests are not very reliable, they had better be negative". A better understanding of the factors which create such views is needed if real safety and perceived safety can both be attained. Comparisons of the risk of taking the drug with the risk of omitting it from treatment are hard to make and harder still to present convincingly. And, ironically, it is not only wicked to do harm with a drug but often unethical to omit to administer it.

In this situation, the role of regulatory authorities is as unenviable as the position of the manufacturers. The regulatory authorities exist to protect the public. The losses incurred by delaying or banning new agents are neither obvious nor, as cold statistics, heart-rending. Occasionally, however, they have been measured. Delay in the introduction of the anticonvulsant drug sodium valproate on to the market in the United States has been estimated to have subjected American patients to approximately one million unnecessary seizures a year at a cost of approximately \$200 million a year⁷⁰. Delay in the introduction of suitable anti-arrhythmic agents has been estimated to cost 10,000 deaths a year in the United States⁷¹.

Other substantial delays in introducing new drugs into the United States as compared with the United Kingdom have been carefully documented: 7 years for the first β -blocking agent for hypertension, 5 and 31/2 years respectively for cromoglycate and inhaled beclomethasone for asthma, 5 years for cotrimoxazole for urinary infections⁷⁰. It is difficult to estimate in every instance how many episodes of illness would have been prevented or treated more effectively if the drugs had been available. But presumably a sufficient quantity of evidence has accumulated in each case to justify the widespread use of the drugs. Why else did the Food and Drug Administration (FDA). in the end approve their use?

Public pressures

Unhappily, the balance sheet is not calculated solely on the best estimates of benefit and risk. Public opinion and political pressure weigh heavily against any suspicion of harm and are comparatively indifferent to benefits unless they are near miraculous. Triazure (azaribine) has been described by the director of the FDA's Bureau of Drugs as "a classic example of a highly effective drug which is useful to a small number of patients with a serious disease (psoriasis) but which also carries a serious risk of harm (thromo-embolism) in a fraction of those who take it" (J. R. Crout cited in ref. 72). It was released by FDA and later withdrawn, and its licensing became the subject of a congressional enquiry. Shubin's account⁷² of the proceedings raises serious questions about the

exercise of medical judgement in a democratic society: clearly safety as a motive over-ruled any question of medical benefit.

Science does not flourish in the political arena, and the problem becomes philosophical: is it better to take risks in the hope of benefit, or to prohibit expected benefits because of an uncertain risk? Specific regulations are not as a rule unreasonable; it is the cumulation of requirements, their inconsistency between nations and their promotion of the mechanical check list as a substitute for reason and responsibility which achieves undoubted harm and uncertain good.

No manufacturer wishes to put unsafe drugs on the market, and it is natural to do what tests appear feasible to ensure safety, but the multiplication of tests of uncertain validity in no way makes them cumulatively any more reliable. It only increases the probability of rejecting useful substances on bogus grounds. It adds to the cost of developing new drugs, which is another way of saying that it diverts resources from discovery to supposed safety testing or, worse, to extensive experiments required to refute some suspicion raised on fashionable grounds but of dubious validity. And it delays the production of new remedies, during which time patients continue to suffer and die for lack of adequate therapy. One must have

sympathy for the industry and regulatory authorities in attempting the impossible tasks of giving complete protection against drug injuries, satisfying the public and defusing those who would make political or financial benefit by exploiting such hazards. But there is no excuse for any parties promoting scientifically worthless or dubious procedures.

Resources are limited, and the diversion of resources in pursuit of safety inevitably reduces the resources available for more constructive purposes. Primum non nocere is a good doctrine for medical students to assimilate, but it is going beyond common sense to refrain from using a substance which may save a hundred lives for every one person whom it harms. It is more than ten years since the words⁷³ were published "... the public and its administative watchdogs have the choice between some risks or no new drugs at all. No problems are avoided by the multiplication of unvalidated tests". But the habit persists of over-reacting to alarming information, of seeking safety without counting the cost of approaching it, of failing to preserve a balanced and scientifically acceptable appraisal of evidence of risk and of benefit. How long will it take for the experts to gain courage and for the unattractive message to be presented to and understood by the public at large?

NEWS AND VIEWS

A new class of contraceptives?

from H.M. Fraser

In the last three years there has been considerable progress towards new contraception based on the use of analogues of luteinizing hormone-releasing hormone (LHRH). They should have an important place as contraceptive agents, for they are innocent of the side effects of steroidal methods, have no metabolic effects and are rapidly inactivated.

The characterization in 1971 of the 10 amino acid sequence of LHRH, by Schally and Guillemin, has led to the synthesis of progressively more potent antagonists and agonists (see the figure). These can inhibit reproductive functions by decreasing or increasing the LHRH stimulus to the gonadotrophic cells in the anterior pituitary gland, modulating the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Surprisingly, the agonists (originally developed to treat infertility) have the more dramatic inhibitory effects. Their effects were first noticed during toxicity trials in rats with high doses of LHRH and its agonists; given daily, they disrupted oestrous cycles, inhibited luteal function and pregnancy and, in males, caused involution of the seminal vesicles and prostate glands and impaired spermatogenesis1-3.

The inhibitory effects of low-dose agonist treatment have since been extended to monkeys4.5 and women6-9. Early attempts to stimulate ovulation in anovular women with chronic therapy led to the finding that pituitary responsiveness is decreased, not increased. This suggested that LHRH might be used to prevent ovulation in normal women, and early studies suggested at least three possible procedures. Ovulation could be inhibited by injecting a LHRH agonist daily throughout the cycle (5 µg per day)6, an inadequate luteal phase could be induced when agonist was given at mid cycle (100 µg per day)7 and luteolysis could be provoked by giving agonist for 2 days in the late luteal phase $(50 \,\mu g \text{ per day})^{8.9}$.

The search for luteolytic agents has been one of the major goals of the contraceptive developers. One obvious advantage of such agents is that a woman would have an otherwise normal cycle. The fact that a luteolysin need only be administered at the end of a cycle would reduce the risk of

toxicity and side effects and also lower cost. But luteolytic agents are often ineffectual when conception has occurred, for their effects can then be offset by the stimulatory effects of human chorionic gonadotrophin (hCG) produced by the trophoblast¹⁰.

There is, however, no question that fertility is prevented when the agonist is administered daily to prevent ovulation. In clinical trials on 30 women in Uppsala¹¹⁻¹³ and 60 women in Berlin^{14,15} using agonist as a contraceptive for 3–12 months, no pregnancies occurred and there were no problems with reversibility. Daily injections are obviously impracticable but agonist can be administered in a nasal spray, although larger quantities (400–600 µg) must then be given.

Continual administration of LHRH agonist produces considerable changes in ovarian steroid production. Because ovulation is inhibited, the progesterone normally produced by the corpus luteum is absent, but this by itself is of little consequence. Variable and unpredictable changes in the most potent female sex steroid, oestradiol-17B, are much more important. It is essential that the oestrogen does not vary outside certain limits: too little, and women may develop menopausal symptoms, too much, in the absence of progesterone, and there will be proliferation of the endometrial lining of the uterus, predisposing it to hyperplastic change.

In about one-quarter of the women studied, the agonist prevented follicular development as well as ovulation, as indicated by consistently low concentrations of oestradiol in the blood¹¹⁻¹⁵. Thus there is little stimulation of the endometrium and women are virtually amenorrhoeic. Fortunately oestrogen was still present in sufficient amounts to avoid problems of oestrogen deficiency in all but a few women.

In the remaining women, ovarian function was less than fully suppressed, follicles still developed and oestrogen rose at varying intervals of time to stimulate endometrial growth. When the oestrogen

levels fall in the absence of ovulation, endometrial bleeding occurs. In a few women, who are presumably even less suppressed, these rises in oestrogen are followed by a small rise in progesterone indicating either ovulation with an inadequate luteal phase or luteinization of an unruptured follicle^{14,15}. In these women, bleeding is more regular.

Many women would object to such alterations of their monthly menstrual patterns. Those who become amenorrhoeic may welcome the opportunity to be free of periods once contraceptive efficiency is ensured.

The safety of chronic agonist treatment hinges on its effects on the endometrium. In the Swedish12 and Berlin study14,15, and in macaque monkeys treated with agonist for more than a year16, there was a spectrum of endometrial activity ranging from inactivity (usually when blood oestrogen was low) to marked proliferation. Although a chronically proliferative endometrium is undesirable, it will be of interest to compare endometrial activity with that of lactational amenorrhoea (low oestrogen, no progesterone) in which many women used to spend much of their reproductive lives without adverse effects.

Regular menstrual bleeding may be achieved by using lower doses of agonist15 or by confining treatment to the early follicular phase²¹, to permit ovulation followed by a defective corpus luteum. This should be incompatible with implantation but there may be some risk of an occasional fertile cycle. The best approach might be to provide exogenous progesterone for a few days at the end of a period of agonist treatment, priming the endometrium and inducing menstruation when withdrawn. Preliminary results of such a regimen are encouraging¹⁷ and although supplementation with progesterone detracts from the idea of completely avoiding exogenous steroids, it is not a return to the 'pill' since no oestrogen is given and progesterone would be administered for a short time only.

The amino acid sequence of LHRH and a widely used agonist.

AGONIST pG1u - His - Trp - Ser - Tyr - G1y - Leu - Arg - Pro - G1yMR₂ $(B\psi^{T})$ $(B\psi^{T})$ $(B\psi^{T})$ $(B\psi^{T})$ $(B\psi^{T})$

H. M. Fraser is in the MRC Reproductive Biology Unit, Centre for Reproductive Biology, 37 Chalmers Street, Edinburgh EH3 9EW.

The use of LHRH agonist as a contraceptive is probably most attractive for women over 35 who do not wish to take the 'pill' because of its minor side effects. as well as the increased risk of cardiovascular problems. The agonist might also prove ideal for lactating women, who would more willingly accept the prolongation of their lactational amenorrhoea, and in whom the combined steroidal oral contraceptive is contraindicated because of its adverse effects on lactation. Agonists used as contraceptives may also, by lowering oestrogen and inducing amenorrhoea, benefit women with menorrhagia or endometriosis while the inhibition of the cyclic progesterone rise may help relieve some symptoms of pre-menstrual tension. There are other therapeutic benefits of chronic agonist treatment, such as control of precocious puberty¹⁸, and they may also be of value in treatment of breast and prostate cancer^{2,3}.

LHRH agonists also in principle permit partners to share the responsibility of fertility control. In a recent trial in men who self-administered daily injections of LHRH agonist for 6-10 weeks, sperm numbers fell markedly19 but, as with other methods that interfere with LH as well as FSH output, testosterone concentrations in the blood also declined, so the treatment was accompanied by loss of libido, impotence and even hot flushes. Thus, testosterone replacement is required and it remains to be seen how effective or practicable this would be. Another problem is that the doses which prevent ovulation in women have no significant effect on the male reproductive function, precluding the use of nasal sprays. But, more efficient methods of delivery of LHRH analogues are expected — subcutaneous implants have already proved active⁵.

The mechanism whereby LHRH agonists exert this 'paradoxical' inhibitory effect remains a puzzle. It is believed that the pituitary is normally stimulated by pulses of LHRH from the hypothalamus to release pulses of LH into the peripheral circulation, which, together with FSH, control gonadal function. On this view, the agonists, some one hundred times more potent than endogenous LHRH, over-stimulate the pituitary with the result that the gonads are exposed to excessive gonadotrophin leading to the 'down regulation' phenomenon. Repeated exposure to agonists, on the other hand, reduces the pituitary's ability to release large amounts of gonadotrophin such as occurs at the pre-ovulatory surge13,20.

This understanding has recently been

complicated by the recognition of direct gonadal actions of LHRH, involving functions which can both stimulate and inhibit steroidogenesis, and the finding of gonadal LHRH receptors.

As things are, LHRH analogues are not the answer to rapid population growth in developing countries because of the mode of administration, yet millions of women are seeking a better alternative to the 'pill'. Moreover, as Djerassi has pointed out22, while we fear the population explosion and demand better methods of contraception, the advent of the 'pill' has also led to an excessive fear of side effects, a suspicion of new developments and an environment in which pharmaceutical companies find it financially impossible to develop new contraceptives. LHRH agonists are not free from problems, but they work, and most important, to millions of women they should be more acceptable than the 'pill'. We should tackle their shortcomings because they are our brightest prospect for a new approach to contraception.

The elixir of life

from an aging correspondent

ALEX COMFORT in his recent article Gerontology in adolescence (Nature 296, 179; 1982) declared that postponing diseases of the elderly beyond the normal life span was probably the area where most advance was likely in geriatric health. Nevertheless, he expressed the hope that an overall neuroendocrine timekeeper will be identified whch may allow modulation of life span itself. It has long been a puzzle why some vertebrate species have long life spans — sulphur-crested cockatoos, for example, have been known to live for 130 years - whereas others are unlikely to survive two consecutive seasons. Moreover, long-lived poikilotherm vertebrates, such as giant tortoises and certain fish, do not stop growing with maturity, and it is these animals that show little, if any, evidence of senescence at the cellular or tissue level. New studies suggest that specific anti-senescence factors sustain the growth of these organisms.

The species which has received most attention from gerontologists is the freshwater carp, Cyprinus carpa. The carp has an ancient lineage of pisciculture - as a source of food in Roman and mediaeval Europe and as ornamental goldfish in the Orient. Their longevity is legendary and has recently been confirmed by carbondating. Dlouhý-Zivot and Ryba (Acta gerontol. (Prag.) 26, 143; 1981) analysed the ratio of ¹⁴C in the vertebrae and scales of two carp weighing over 30 kg taken from the fish pond of Gregor Mendel's former monastery near Brno; it was evident that

these same fish had been lurking in the muddy depths several years before Mendel first bred his peas only 100 m away. The European carp grows very slowly and it would appear that the long, cold winters aid its longevity. In Israel, where carp are an important source of protein, the fish grow very much faster, but attempts to keep long-lived carp as founder-breeders for commercial strains had not, until recently, been successful in the Galilean climate (Lechaim et al. Israel J. Piscicult. 12, 86; 1979).

The endocrine basis of growth and senescence in the carp has long been the focus of attention of Obispo and his colleagues in the Stoyte Institute of Life Sciences at Tarzana College, California. Boone and Obispo (Am. J. Nutr. 42, 1213; 1960) first investigated factors in the gut because of Hauberk's remarkable claim some 125 years earlier at the age of 92 (Phil. Trans. R. Soc. B103, 397, 183; 1834) that addition of raw carp viscera to the diet each Friday prolonged fitness and sexual vigour. Obispo and Maunciple (Am. J. Nutr. 58, 82; 1967) extracted a protein factor from the intestine of carp which significantly extended the life span of gnotobiotic mice. After many a summer's hard work, detailed analysis revealed that the factor is a small protein, named longevin, comprising two dissimilar subunits, a hexadecapeptide A-chain and an icosapeptide B-chain linked by disulphide bonds (Maunciple et al. J. molec, Endocr. 2; 575; 1976). The activity of longevin is

extremely heat labile on account of the instability of the B-chain. Three years ago Obispo's group made the notable discovery (Eldestez et al. J. molec. Endocr. 5, 902; 1979) that the B-chain was synthesized by Escherichia coli in the visceral flora of the carp whereas the A-chain was released from neuroendocrine Kultschitzky-like cells in the gut wall.

At last month's meeting of the International Gerontological Society in Athens, Obispo announced that the B-chain gene had been cloned and sequenced. Furthermore, by manipulating the sequence to code for lysine in place of arginine three residues from the C-terminus, a heat-stable molecule was obtained which still forms a functional complex with the A-chain. When bacteria expressing the modified B-chain gene in a mobilizable plasmid were introduced into 18 month-old specificpathogen-free mice, prolongation of the life span was observed (Proc. natn. Acad. Sci.; in the press). Apparently the modified B-chain forms functional complexes in the mouse gut with a host hexadecpeptide homologous to that of the carp. Introduction of the B-gene into mice genetically predisposed to progeria did not result in delayed aging, suggesting that the host A-chain was deficient in these mice.

Some peculiar side effects were noted in mice colonized by bacteria producing longevin B-chain. The pelage on the body was replaced with scales as on the tail, and about 20 per cent of the mice developed multiple carcinoid tumours of the colon. These tumours release large amounts of longevin A-chain, as well as serotonin. A cDNA library has been prepared from the tumour cells and Obispo is confident that his laboratory has already identified the A-chain gene by co-transfection of the cDNA library together with the cloned B-chain gene into senescent MRC-5 cells. He is optimistic that the administration of a plasmid containing both A- and B-chain genes into the gut flora of mice will prolong life without inducing tumours, or hopefully the scaly skin. Although he has patented the B-chain clone, he admits that treatment of humans is still some years away.

The carp is unlikely to be the only source of longevin B-chain. Gerontologists are intrigued by the unusually long life spans of cold-water fishing communities as far apart as the Falkland Islanders and the Aleut Indians (Whiting et al. WHO World Nutrition Rep. No.5, 110; 1980), where raw krill is an important source of vitamins A. D and E. In northern Hokkaido, Furō and Choju (Jap. Jl Publ. Hlth 17, 646; 1975) reported exceptional vigour among the elderly fisherfolk who eat whole salted sprats. And the parish registry on Canna in the Inner Hebrides reveals several centenarians in the nineteenth century when kippers were smoked and eaten without evisceration (Gonister J. comp. Nutr. 29. 82; 1978). Long life is a fishy business indeed.

Cancer genes — processed genes — jumping genes

from Peter Newmark

New data, some of it just published and some presented at a meeting* four weeks ago, illustrate the growing convergence of opinion on the activation of certain cellular genes (transforming genes) as the molecular basis of cancer. Whilst there is undoubtedly a danger of oversimplifying and generalizing from these studies, there is no doubt that they deserve attention, not least because of speculation that the genetic changes associated with cancer might be better understood in the light of our dramatically changed notions of the stability of the eukaryotic genome.

A variety of evidence strongly supports the view that, within the human genome, there are genes whose activation from dormancy or, at most, low-level expression is associated with the conversion of a normal cell into a tumour cell. Part of the evidence is the isolation, from human cells, of DNA sequences and RNA transcripts which cross-react with the transforming genes of tumour viruses of animals. But the most dramatic evidence of recent times is that it is possible, occasionally, to extract from human tumour cells, DNA that will transform cultured mouse fibroblasts into cells which, like tumour cells, form foci in culture and can induce tumours in mice. This DNA is said, therefore, to consist of, or to contain, a transforming gene. (It should not be overlooked, however, that these fibroblasts, NIH 3T3 cells, are not normal in all respects. Like tumour cells they are immortal in culture and they tend spontaneously to form foci in culture even before transfection with DNA from a tumour cell. What is more, they are the only type of cell that can reliably be transformed by human DNA.)

In Houston, M. Wigler (Cold Spring Harbor) outlined his group's progress (much of which appears on p.404 of this issue) in isolating and characterizing one transforming gene and R. Weinberg (Massachusetts Institute of Technology) described parallel studies with what is probably the identical gene from a different tumour. Each group started with a different human bladder carcinoma cell line and ended up with a very similar cloned fragment of DNA that retained the ability to transform NIH 3T3 cells. And both groups have used this fragment to detect similar sequences in the DNA of normal human tissues, implying that the transforming genes of tumours are neither the result of a major modification of normal genes (for example by rearrangement) nor the result of genetic import (for example, by a tumour virus).

Further support for the lack of major modification comes from Weinberg's failure to detect any differences in the way eight restriction enzymes cut the transforming gene and its normal counterpart. Wigler, however, does find some small differences but there are as many between different tumour cell lines and between different normal human placentas as there are between tumours and normal tissues. This extensive polymorphism, Wigler speculates, is due to the presence of a variable number of copies of a short sequence of DNA in the environs of the transforming gene.

It is generally assumed that transforming genes are transcriptionally inactive in normal tissue and that cell transformation is a consequence of their activation, by whatever means. Not surprisingly therefore, Wigler finds transcription of the bladder transforming gene in the cell line from which it can be transferred to NIH 3T3 cells but not in normal tissue. More surprising was his claim in Houston that transcription of the bladder gene could be detected in every tumour cell line examined, including some which have a transforming gene different from that of the bladder cell line. Both Wigler and Weinberg have extracted at least three distinct transforming genes from human cell lines derived from different tissues but have found no definite correlation between the tissue and gene types (in addition to the bladder carcinoma gene, Wigler has also cloned the distinct transforming gene of a lung carcinoma cell line).

What is the basis of the transcriptional activation of the transforming genes? One rather unlikely possibility is that it is the result of amplification of the gene. There is evidence of amplification of mammalian transforming genes on an evolutionary time scale (Chattopadhyay et al. Nature 296, 361; 1982) but on a developmental time scale there are few examples of amplification (the most recent of which is the transient amplification of chicken actin genes during myogenesis - see W.E. Zimmer and R.J. Schwartz in Gene Amplification ed. Schimke, R.T.; Cold Spring Harbor Laboratory, New York; 1982). Both Weinberg and Wigler have explored the possibility of amplification in a panel of human carcinoma cell lines with their transforming gene probes. Weinberg finds no more than a twofold difference and Wigler at most a fivefold difference between different cells with his bladder gene probe and none with his lung gene

Peter Newmark is Deputy Editor of Nature.

^{*&}quot;Perspectives on genes and the molecular biology of cancer"; the 35th Annual Symposium of Fundamental Cancer Research, held at Houston, Texas, on 2-5 March 1982.

probe. The evidence for gene amplification as a basis of transcription is therefore weak, particularly since even apparent amplification may in fact be the result of the presence of pseudogenes or of abnormal numbers of chromosomes.

It is much more likely that transcriptional amplification is the result of switching the transforming gene on (or up) by, for example, a mutation or insertion in a site that regulates transcription. In theory that could be revealed in a matter of months when the sequences of the transforming gene from bladder tumour cells and normal cells will be available for comparison but it may be difficult immediately to prove that any change of sequence is responsible for increased transcription.

Such is the situation in bursal lymphomas of chickens. There is good evidence that these are caused by the integration of avian leukosis virus (which does not carry a transforming gene) into the host genome in such a way that a cellular transforming gene comes under the influence of a viral promoter. The problem arises from the fact that the inserted promoter need not be in the expected position — just upstream of the transforming gene — but may also be downstream or even in the 'wrong' orientation (Nature 295, 209; 1982). By way of indicating that this well documented system is not unique, Harold Varmus (University of California, San Francisco) presented evidence of the localization of murine mammary tumour virus sequences within the same 6 kilobase fragment of the genome of 5 out of 35 mammary tumours caused by the virus. This localization is reminiscent of, if less frequent than, that of avian leukosis virus sequences in bursal lymphomas. So far, however, Varmus has no evidence that the 6 kilobase site contains a transforming gene or produces any transcripts.

The cellular transforming gene which is activated by avian leukosis virus is one of a class of such genes that are defined by their relationship to the transforming genes carried by many acute tumour retroviruses. (So far there is no evidence, but some expectation, that these cellular transforming genes, and those exemplified by Wigler and Weintraub, are of the same class.) It is assumed that viral transforming genes are derived from the mRNAs of cellular transforming genes. This assumption fits with the fact that both the viral genes and mRNAs lack the introns of the cellular genes. Howard Temin (University of Wisconsin-Madison) described such a case in which the rel oncogene of reticuloendothelial virus (strain T) has clearly been derived from the mRNA of a cellular oncogene that is found in birds (but not mammals). The cellular gene occupies a very big stretch of DNA because of its introns and in the turkey, the gene is highly polymorphic, perhaps because of deletion/insertion events in the introns.

The discovery of what Philip Leder (NIH and Harvard Medical School)

dubbed 'processed genes' strongly suggests that transforming genes are not the only cellular genes that can be re-integrated into chromosomal DNA. Like viral transforming genes, processed genes have a sequence closely resembling the coding sequence of a cellular gene. What was probably the best case of a processed gene, that of α -globin (Lueders et al. Nature 295. 426; 1982), has now been superseded by the case of human immunoglobulin λ light chain (Hollis et al. Nature 296, 321; 1982). This processed gene terminates in a long sequence of adenosines, like the 'poly(A)' tail of the mRNA from which it must surely have been derived by reverse transcription and integration. (Note, however, that the mRNA in question appears to have been derived from an incomplete, abnormal transcript.)

But the most striking processed gene will be that of human β -tubulin (Wilde et al. Nature; in the press). It appears to have been derived from a complete transcript. It lacks introns and has a poly(A) tail. And, it is bounded by a directly repeated 11 base pair sequence. This reminds one of the sequences that flank all transposed genes and make it yet more likely that the gene was integrated as supposed.

Another hallmark of a processed gene is

that it can be located far from the parental gene, even on a different chromosome. M. Birnsteil (University of Zurich) raised the possibility that a gene could pass not just between chromosomes but between species. In analysing the histone genes of various species of sea urchin, his group has come to the startling conclusion that within the last million years, a cluster of histone genes jumped from one species to a distantly related species with which it lives in the Atlantic Ocean. How else is one to explain the fact that there is little difference between the third base positions of one histone gene cluster of the two species whereas the difference between other clusters in these and other species is always reasonably great and consistent with a fixed rate of change with evolutionary time (M. Busslinger et al. The EMBO J. 1, 27; 1982). Was this also a virally mediated jump?

In several ways, therefore, loose but tantalizing threads hold together the genetic mechanisms of cancer and evolution. The links may be illusory but even if they vanish with time, it is more than likely that others will be forged as molecular biologists continue, in Leder's modest description, "to stumble" across new varieties of genomic fluidity.

Geomagnetic cores and secular effects

from D.H. Tarling

ALTHOUGH the geomagnetic field was the subject of the earliest scientific treatise (Gilbert's De Magnete of 1600) it still remains the most enigmatic of all the Earth's properties. The situation is even more extraordinary when it is realized that it is also the only geophysical property whose value can be determined for past times by direct measurements of rocks at the Earth's surface. Although the lack of progress reflects, in part, the complexity of the magnetohydrodynamic equations that govern core processes, the chief problem given the number of geomagnetic models available for testing - must be seen as a lack of data.

The problem has been partially resolved in this century by the establishment of geomagnetic observatories and by the increasing number of field studies, supplemented by satellite monitoring. The present geomagnetic field is now quite well known, but the long-term changes in the field, recorded in rocks, are not—they have mainly been studied for other purposes, particularly geological and archaeomagnetic dating. A recent meeting at the Royal Society of London* was thus significant in

concentrating a variety of minds on defining magnetic data in terms of core processes and complementing seismic, geochemical and geomagnetic data with theoretical considerations.

There are, in fact, numerous observations of the geomagnetic direction, especially declination (and to a lesser extent intensity), available from observations in the 18th and 19th centuries. Thompson (University of Edinburgh) and Malin (Institute of Geological Sciences, Edinburgh) have re-examined much of these data with somewhat surprising results. It seems that the lifetime of the components of the non-dipole field (isoporic foci) decay in much shorter periods, some 500 years, than had been previously thought. The present westward drift of the field has been occurring on a world scale for most of the past 400 years and a change in the sign of the quadrupole component occurred in 1820. Studies of lake sediments (Creer, University of Edinburgh; Barton, University of Rhode Island) and archaeological materials (Kovacheva, Bulgarian Academy of Science; DuBois, University of Arizona) show clearly that intervals of both eastward

^{*}The meeting entitled "The Earth's Core: Its Structure, Evolution and Magnetic Field" was held on 27-28 January 1982.

and westward drift have occurred. Creer found evidence for both correlations and lack of correlations in lake sediments from Europe and North America which Thompson explained as the simple growth and decay of non-dipole features stationary components arising where two non-dipole components of the same sign are interacting. The presence of both clockwise and anticlockwise rotations over archaeological periods means that the westward drift cannot be adequately explained by a persistent faster rotation of the mantle relative to the core. However, the rate of secular variation and the rate of rotation of the Earth are clearly coupled, as indicated by the 1969 'jump' in secular variation (Barraclough, Institute of Geological Sciences, Edinburgh), but the lunar tidal deceleration of the mantle of 1.78 ms per century may be accompanied by a nontidal acceleration of 0.8 ms per century (Runcorn, University of Newcastle) attributable to a continued but very slow growth of the core, as also suggested on geochemical grounds (Allegré, University of Paris).

All geomagnetic models are constrained by the need to allow polarity reversals. It is generally agreed that reversals occurred randomly during over the past 48 million years but may have occurred more systematically before that. However, it is probable earlier reversals have simply not been dated with sufficient precision. Lowrie (University of Zurich) and Channell (Lamont-Doherty Geological Observatory) presented improved biostratigraphical dating of reversals in the Mesozoic that are vital for establishing world-wide correlation scales. Unfortunately, analyses of the geomagnetic polarity frequency still require conversion of the biostratigraphical time scales into an accepted radiometric ('absolute') scale. The new radiometric decay constants for K/Ar have been designed to give a greater uniformity in radiometric ages determined by different methods (Steiger & Jager Earth planet. Sci. Lett. 36, 359; 1977), but consistent errors of several per cent can still arise in establishing the radiometric age of biostratigraphical horizons (Tarling & Mitchell Geology 4, 133; 1976). Careful analyses and assessments are therefore necessary before the polarity frequency in the early Tertiary and Mesozoic can be considered to be established.

Polarity transitions are likely to provide key diagnostic information on the processes operating in the geomagnetic dynamo but have proved very difficult to study. Thin slices of oceanic sediment cores can be used to determine more precisely the changes at specific locations along a line of longitude (Opdyke, University of Miami), but observations are mostly confined to the last geomagnetic transition and to the Northern Hemisphere (Hoffman, California Polytechnic). Sediments can, in any case, be disturbed by non-geomagnetic effects and Verosub (University of California Polytechnic).

fornia, Davis) remains rightly unconvinced about much of the available sedimentary evidence for most polarity excursions, even though some undoubtedly exists. Even records in igneous rocks may be dominated by rock magnetic factors, such as in the Laschamp-Olby excursion (Heller, University of Zurich), and studies of igneous sequences, without adequate radiometric control, can also be misleading. It is now clear that the 'dipole window' in the Pacific did not exist over the past few million years or so, but is simply an artefact of the very rapid eruption rates in Hawaii (McWilliams, University of Stanford), although the corresponding palaeomagnetic poles continue to be slightly 'far-sided' and right-handed, as in Iceland, posing problems in any interpretation of the average geomagnetic field (Harrison, University of Miami).

The geomagnetic dynamo does not require a large driving energy and sufficent could be provided by the solidification of the inner core. The outer core is probably enriched in carbon, sulphur and oxygen (Ahrens, Caltech), so it is likely that further energy is provided by the incorporation of some radiogenic heat-producing elements, such as K, Th and possibly U. The core has generally been neglected in considering the distribution of lead and anomalies found in rocks derived from the mantle have often been interpreted as showing that mantle convection could not take place. Allegré considered that the core could, in fact, be a major factor in the continuing evolution of the core and mantle.

The evidence for actual motions in the core was somewhat controversial, with LeMouel (University of Paris) considering that there are clear signs, in geomagnetic measurements, for such motions, while these were not seen by Gubbins (University of Cambridge). The most provocative point concerned whether or not there are 'bumps' on the core-mantle interface. These are now more closely defined by the seismic evidence (Bolt, University of California, Berkeley), particularly when observed signals are compared in both amplitude and shape with theoretical seismograms. The 'scattering structures' appear confined very closely to the coremantle boundary with lengths some 10-30 km and heights of a few 100 m - if they are topographical 'bumps' (Haddon, Bureau of Mineral Resources, Ottawa). However, they could equally well mark zones of temperature or physical differences rather than topographical boundaries. Either explanation may, of course, also be linked to the convective pattern in the mantle (Hide, Meteorological Office, Bracknell). The presence of numerous bumps may cause an increased amplitude in secular variation and also an increased probability of reversals of polarity, and quieter magnetic periods, on a geological time scale, may be associated with fewer bumps. This demonstrates, yet again, the need for closer examination of the palaeomagnetic records to see whether there really is any correlation between the magnitudes of secular variation and the frequency of polarity transitions.

A galaxy for quasar 3C48

from R.F. Carswell

THE superb observations by Boroson and Oke reported in this issue of *Nature* (see p.397) reveal that the faint nebulosity to the north and south of the quasar 3C48 is dominated by starlight and that the stars have a redshift close to that determined from the broad emission lines in the quasar spectrum. This provides the first direct evidence that a quasar is associated with a galaxy and lies at a distance corresponding to its redshift, adding to the weight of evidence against non-cosmological quasar redshifts.

Most quasars are so far away that there is little hope of detecting galaxies which might be associated with them, but for a number of low-redshift examples, faint surrounding nebulosity has been found. The difficulty has then been to establish that this extended emission arises from starlight and not from a large gaseous envelope which radiates only in emission

R.F. Carswell is in the Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge CB3 0HA. lines. A number of attempts have been made to do this, by obtaining spectra of the nebulosity to search for the stellar absorption lines typical of galaxies, but until now the results have been somewhat unconvincing.

While Boroson and Oke's work confirms a few widely held beliefs, the results also contain surprises. The first, and most obvious, is the discovery that the stars in the 3C48 galaxy are not quite like those in a normal galaxy such as our own. They appear to be bluer, and younger, than usual, similar to those in galaxies where recent bursts of star formation are thought to have occurred. Estimates of age are difficult, but the brightest part of the stellar population in 3C48 is probably 100 million to a billion years old. If the stars have formed recently we would expect the system to be rich in gas, and certainly the material presented by Boroson and Oke shows, through emission lines in the spectra of the nebulosity, that there is still much gas present. The galaxy could thus be a gas-rich spiral rather than an elliptical which has little interstellar material, though given the distance of 3C48 it will be very difficult to confirm the presence of spiral structure.

It is also tempting to suggest that those quasars with strong emission lines are formed in spiral (that is, gas-rich) galaxies. In all cases, only very small amounts of gas are needed very close to the quasar to explain the line strengths seen, but then only a small amount of the available gas will be in the immediate quasar neighbourhood. BL Lac objects, which are really quasars with no emission lines and therefore probably little gas in their neighbourhood, could similarly be in the centres of elliptical galaxies (which have a low gas abundance). The late-type stellar spectrum recently found for the nebulosity around BL Lac is itself suggestive in this regard. If young stars do generally dominate the quasar stellar spectrum, this incidentally helps to

explain why previous searches for starlight have failed. Most of these have looked primarily for the usual strong Ca II feature typical of a later population, which is weak or absent in the 3C48 spectrum. But much work remains to be done before this can be established; one object, however important, is hardly a statistical sample!

Another interesting, and more puzzling, result is that the redshift of the quasar determined from the galaxy starlight does not agree very well with that determined from the sharper emission lines in the quasar spectrum. While it is not unusual for the different broad emission lines to give rather different redshifts, the sharp lines are believed to arise in a more extended region and so to give a better redshift estimate. Here the sharp lines differ from the galaxy redshift by about 400 km s⁻¹ while the broad hydrogen lines agree very well. It is possible that a combination

of velocity flow and obscuration of the clouds shifts the sharp lines significantly, but the required shift is so large (comparable with the line widths) that it is rather difficult to explain simply.

Another surprise is simply one of observational detail. The spectra Boroson and Oke obtained for two regions of the nebulosity around 3C48 took a total of only two hours of telescope time, while others in the past have unsuccessfully devoted much longer periods of time to similar projects. A combination of an efficient spectrograph and a modern charge-coupled device as a detector has allowed them to obtain useful spectra of faint objects quickly. With such a system available one hopes, and expects, that similarly exciting discoveries will continue to be made at Palomar, and that Boroson and Oke will be able to follow up their observations by examining the nebulosity around other quasars.

100 years ago

THE WINGS OF PTERODACTYLES

The first Pterosaurians discovered were recognised as flying animals, but were thought to be bats. As soon as their general structure became known, they were classed with the reptiles, although it was considered possible that their power of flight was due to feathers. Later their bones were mistaken for those of birds by various experienced anatomists, and others regarded them as sharing important characters with that group. Some anatomists, however, believed that the fore-limbs of pterodactyles were used for swimming rather than for flight, and this view has found supporters within the present decade. A single

fortunate discovery, made a few years since, has done much to settle the question as to the wings of Pterodactyles, as well as their mode of flight, and it is the aim of the present article to place on record some of the more important facts thus brought to light.

The specimen to be described was found in 1873, near Eichstädt, Bavaria, in the same lithographic slates that have yielded Archoeopteryx, Compsognathus, and so many other Jurassic fossils known to fame. This specimen, which represents a new species of the genus Rhamphorhynchus, is in a remarkable state of preservation. The bones of the skeleton are nearly all in position, and those of both wings show very perfect impressions of volant membranes still attached to them. Moreover, the extremity of the long tail supported a separate vertical membrane, which was evidently used as a rudder in flight. These peculiar features are well shown in Fig. 1, which represents the fossil one-fourth the natural size.

A careful examination of this fossil shows that the patagium of the wings was a thin smooth membrane, very similar to that of modern bats. As the wings were partially folded at the time of entombment, the volant membranes were naturally contracted into folds and the surface was also marked by delicate striae. At first sight, these striae might

Fig.3 Restoration of Rhamphorhynchus phyllurus.

readily be mistaken for a thin coating of hair, but on closer investigation they are seen to be minute wrinkles in the surface of the membranes, the under-side of which is exposed. The wing membranes appear to have been attached in front along the entire length of the arm, and out to the end of the elongated wing finger. From this point the outer margin curved inward and backward, to the hind foot.

The membrane evidently extended from the hind foot to near the base of the tail, but the exact outline of this portion cannot at present be determined. It was probably not far from the position assigned it in the restoration attempted in the cut given below, Fig. 3. The attachment of the inner margin of the membrane to the body was doubtless similar to that seen in bats and flying squirrels.

In front of the arm there was likewise a fold of the skin extending probably from near the shoulder to the wrist, as indicated in Fig. 3.

The present species appears to be most nearly related to *Rhamphorhynchus Gemmingi*, von Meyer, from the same geological horizon, and near the same locality. That it is quite distinct, however, is shown, aside from the difference in size, by the complete ankylosis of the scapula and coracoid, and by the fifth digit of the hind foot being well developed, and having three phalanges. In the name *Rhamphorhynchus phyllurus*, here proposed for the species, the latter designation refers to the leaf-shaped caudal appendage, which appears to be one of its most characteristic features.

For the long delay in the description of this important European specimen, the writer can only plead *l'embarras des richesses* nearer home.

ARTICLES

Detection of the underlying galaxy in the QSO 3C48

Todd A. Boroson & J. B. Oke

Palomar Observatory, California Institute of Technology, Pasadena, California 91125, USA

Spectra have been obtained of the faint nebulosity north and south of the centre of the QSO 3C48. In addition to the emission lines previously known, a continuum dominated by hot stars is seen at both positions. This suggests that the host galaxy is a spiral and may explain why searches for features indicative of an old stellar population in QSOs have been unsuccessful. The redshift of the underlying galaxy is the same as that of the permitted lines in the QSO but differs from the redshift of the forbidden lines in the QSO by 500 km s⁻¹.

THE QSO 3C48 has long been known to be associated with wisps of nebulosity. These extend predominantly north and south from the central object and have been well illustrated by Sandage and Miller¹. Although it has been argued that QSOs occur in the nuclei of galaxies and that the underlying galaxy should be visible in some cases², this identification of the nebulosity in 3C48 has been questioned for two reasons. First, its radial extent and total luminosity are uncharacteristically large for a normal galaxy³. Second, the spectrum of the fuzz has been obtained by Wampler et al.⁴ who found no evidence for starlight. They did detect emission lines from [O II], [O III], and [Ne III] at a slightly larger redshift (0.370) than that of the same lines in the QSO (0.368). Subsequently, Bergeron⁵ modelled the spectrum of the nebulosity with an extended gaseous disk, ionized by the QSO.

Observations

We observed 3C48 and the surrounding nebulosity on two nights, 4 November and 16 December 1981 with the Hale 5-m telescope. Instrumentation consisted of the double spectrograph with an RCA 320×512 CCD on the blue camera and a Texas Instruments 800×800 CCD on the red camera. The blue camera exposures were of poor quality and will not be discussed. The grating was set to give coverage from $\lambda\,5,000$ to $\lambda\,10,000$ with the red camera, yielding about 6 Å per pixel. A slit 2 arc s wide, orientated in the east—west direction was used in all exposures.

On 4 November 1981, we obtained a 500-s exposure of the nucleus and a 3,000-s exposure centred 2 arcs north of the nucleus of 3C48 in 2 arcs seeing. On 16 December 1981, we obtained an additional 500-s exposure of the nucleus and a 3,000-s exposure with the slit centred 2 arcs south of the nucleus. The seeing on the second night was 1 arc s. Comparison lamp spectra were obtained on each night immediately after each pair of exposures of 3C48.

The data were reduced by first correcting the twodimensional image for bias level and small scale sensitivity variations. The sky spectrum was then determined and subtracted and a 4 arcs wide swathe was extracted to create a one-dimensional spectrum. The comparison lamp spectra were similarly extracted and fit with a cubic wavelength polynomial. Residual errors from these fits were <0.20 Å for each of nine comparison lines. Finally, the nuclear and nebulosity spectra were corrected approximately to absolute fluxes using observations of spectrophotometric standards obtained on each night. All observations were made within 15° of the zenith so atmospheric refraction effects are negligible.

Figure 1 shows the nuclear spectrum obtained on the first night and the spectra of the two regions in the nebulosity. The strongest lines in the nucleus have been labelled. The spectrum of the north nebulosity is contaminated by scattered light from the nucleus. This can be seen from the broad H β and H α and from the Fe II complexes. Attempts to remove this contamination by subtracting a fraction of the nuclear spectrum from the north nebulosity spectrum showed that this technique is incapable of removing the scattered light at all wavelengths. Because many of the strong features expected in the integrated light from stellar populations are between $\lambda 3,900$ and $\lambda 6,000$ we limited our efforts to this spectral region. We found that the subtraction of 1.4% of the nuclear spectrum from the north nebulosity removes all traces of the broad nuclear lines except for $H\alpha$. This corrected north-nebulosity spectrum and the uncorrected south-nebulosity spectrum, which appears essentially free of scattered light from the nucleus, are shown in Fig. 2. For ease of identification of features, the spectra are plotted against rest wavelength, assuming a redshift of 0.370. We have not plotted the spectral region longward of $\lambda 5,500$ where the data become quite noisy and the residual contamination by the nuclear scattered light may be considerable.

Results

Figure 2 shows that in addition to the emission lines seen by Wampler et al.⁴ a continuum with absorption features is present in both north and south spectra. These absorption features consist primarily of the higher Balmer series lines and the Ca II K line at $\lambda 3,933$. H β appears to be completely filled in by emission and H γ partially so. None of the absorption features indicative of late type stars, particularly the G band ($\lambda 4,300$), Mg b ($\lambda 5,175$), or the Na D lines ($\lambda 5,890$), are seen. The [O I]

			± 0.0003	±0.0002		

^{*} Means for nucleus are average of both runs.

 $\lambda 6,300$ line, which is outside the spectral limits of Fig. 2 is also present in the nebulosity. It can be seen in Fig. 1 to be much stronger in the north-nebulosity spectrum than in the nuclear spectrum. The nebulosity apparently shows the spectrum of a hot stellar population, with a mean spectral type of about A7 as judged from the relative strengths of He and Ca II K and from the strengths of the higher Balmer lines. The continuum slope is also indicative of blue stars. The approximate B-V colours are 0.35 for the north nebulosity and 0.22 for the south nebulosity. These estimates are probably only accurate to ± 0.1 mag.

It was pointed out by Wampler et al.⁴ that the forbidden lines in the fuzz have a slightly higher redshift than those in the nucleus. Similarly, Thuan et al.⁶ found a discrepancy between the redshifts of permitted and forbidden lines in the nucleus. Therefore, we have measured the redshifts of all reasonably strong and sharp lines in the nucleus and in the nebulosity: these are listed in Table 1. All the lines in each nebulosity spectrum have the same redshift. Both of these redshifts are consistent with the redshift of the permitted lines in the nucleus. The forbidden lines in the nucleus, however, have a velocity which is, in the rest frame of the QSO $(\Delta z/(1+z))$, $330\pm78\,\mathrm{km\,s^{-1}}$ less than that of the permitted lines and $481\pm$

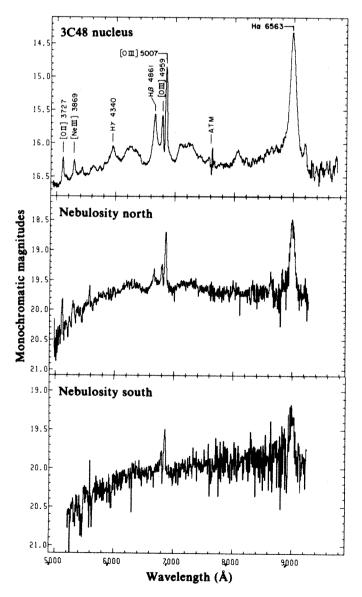

Fig. 1 Spectra of the nucleus of 3C48 and two regions in the nebulosity. The strongest spectral features in the nucleus are labelled. The feature ATM is due to the atmospheric A band.

 $106~\rm km~s^{-1}$ less than the mean of the redshifts of the two regions in the fuzz. The uncertainties quoted are derived from the mean errors in averaging the redshift determinations from the various lines.

Discussion

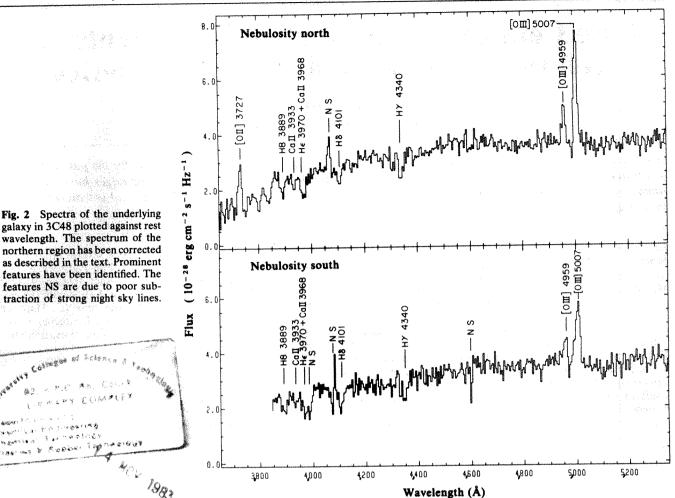

Several recent studies have used imaging techniques to produce evidence for extended structure in low redshift OSOs7 identification of this fuzz with galaxies, however, rests on circumstantial evidence. The few objects in which the nebulosity has been observed spectroscopically have shown only emission lines, that is, no evidence of a continuum or absorption features indicative of stars^{4,9-11}. The one possible exception to this is 3C206; the fuzz around it shows a red continuum with Ca II H and K absorption¹². However, other absorption lines expected to be strong are absent. Also, attempts to show the connection with galaxies by observing the highly diluted stellar features in the nuclei of QSOs have been unsuccessful¹³, unlike similar studies of N galaxies and BL Lac objects^{14,15}. Thus, the discovery of unambiguous stellar absorption features in the fuzz around 3C48, a fairly luminous QSO ($M_V = -25.3$ for $q_0 = 1/2$) is a crucial link in relating QSOs to active galactic nuclei and to normal galaxies.

The immediate goal of identifying the fuzz around QSOs is to ascertain the properties of the regions in which QSOs form. In that regard the early spectral type of the underlying galaxy is unexpected. In general, of course, blue colours and recent star formation are indicative of spiral galaxies as opposed to ellipticals. However, there are elliptical galaxies with young stars, NGC1275, for example 16. Also, the average B-V colour of the fuzz, 0.28 is bluer than a typical galaxy of even the latest type 17. The mean B-V colour for Sc galaxies is 0.51 (ref. 17), more than 0.2 mag redder than is observed in the fuzz of 3C48. The presence of gas required to explain the emission lines also argues against the host galaxy being an elliptical as these usually have little or no detectable gas 18.

The surprisingly blue spectrum of this nebulosity raises the question of whether this is a common phenomenon in galaxies in which QSOs reside, perhaps because shocks emanating from the central source trigger global bursts of star formation. It is clear that the spectrum is really dominated by the hot stars as there is no evidence for a cooler population even at Mg I b $\lambda 5,175$ or Na D $\lambda 5,890$ where the old population should contribute a larger percentage of the integrated light than in the blue. The single burst models of stellar populations calculated by Larson and Tinsley¹⁹ have B-V colours in the observed range after $1-2\times10^8$ yr. However, the mean spectral type of A7 at $\lambda 4,000$ argues for an age more likely 10^9 yr. This discrepancy, if real, may indicate a very flat initial mass function which would produce a slower reddening in B-V with age¹⁹.

Another aspect of the extreme youth of the stellar population is the total luminosity of the underlying galaxy. It has been suggested in previous work that the nebulosity is too luminous to be a galaxy3. We estimate that the total apparent magnitude is 18.5 or brighter at $\lambda 5,500$ in the rest frame of the galaxy; this corresponds to an absolute visual magnitude of -23.0 $(H_0 = 50, q_0 = 1/2)$. While this is particularly luminous for a normal spiral or elliptical galaxy, the blue colour corresponds to a population with a mass-to-light ratio, $M/L_{\rm V}$, at least a factor of 10 smaller than those typical of older populations¹⁹. Thus, this galaxy could have become as much as 3 mag brighter because of the presumed burst of star formation. If this is not unusual, that is, if QSOs frequently occur in gas rich galaxies in which they trigger global episodes of star formation, the technique of searching for weak stellar absorption features in the nuclei of QSOs may be futile.

Wampler et al.⁴ observed the north nebulosity at twice the distance from the nucleus of the observations described here. They found no evidence for the stellar continuum at the more distant position, but did find emission lines from forbidden

transitions of OII, OIII, and NeIII. They and later Bergeron⁵ argued that the emitting gas was ionized by the QSO. Bergeron's detailed analysis had trouble explaining the absence of $H\beta$ emission which seemed to rule out heating by a Lyman continuum source. In our spectra, it is clear that the apparent absence of H β emission is due to the presence of H β absorption in the underlying continuum and also that the intrinsic strength of the $H\beta$ emission is approximately the same as the [O III] \$4,959 line. In support of the idea that the ionization is due to a power law continuum, we note the strong presence of three levels of ionization of oxygen; we have not, however, performed a detailed analysis of the line strengths.

One of the peculiar aspects of the fuzz is the redshift discrepancy. Table 1 shows that the forbidden lines in the QSO are 300-500 km s⁻¹ blueshifted from both the permitted lines in the QSO and all of the lines in the underlying galaxy. Presumably, then, it is these forbidden lines in the QSO which differ from the systemic redshift. This phenomenon has been seen in Seyfert I systems and QSOs previously^{6,20} but it has never been clear which lines, the forbidden or the permitted, represent the systemic velocity. Explanations proposed for this discrepancy include models with infalling or outflowing gas in which one side of the region is preferentially seen because of dust mixed with the gas or light travel time arguments20-22

Conclusion

We have detected stellar absorption lines in the nebulosity around the QSO 3C48. The integrated light from this population has both a B-V colour and absorption features indicative of middle to late A stars, suggesting that the underlying galaxy is a spiral in which a massive star formation burst was triggered at least 10^8 years ago. The [O II] $\lambda 3,727$ and [O III] $\lambda 4,959$ and $\lambda 5,007$ emission lines seen by Wampler et al. as well as [O I] $\lambda 6,300$ are also present. The underlying galaxy must have an absolute magnitude of -23, or brighter but without the recent burst of star formation it would be at least 2 mag fainter. The redshifts of both absorption and emission lines in the fuzz are inconsistent with the forbidden lines in the nucleus but, within measurement errors, are the same as that of the permitted lines. This indicates that the nuclear forbidden lines are blueshifted 300-500 km s⁻¹ with respect to the systemic velocity.

This work was supported by NASA through grant NGC-05-002-134.

Late Cenozoic uplift of stable continents in a reference frame fixed to South America

A. G. Smith

Department of Earth Sciences, Downing Street, Cambridge CB2 3EQ, UK

A reference frame fixed to South America may approximate to an 'absolute' reference frame for the past 100 Myr. In this frame, otherwise stable continents that have moved onto the former positions of oceanic ridges have experienced rapid plateau uplift, probably caused by phase changes in the continental mantle, and occasional volcanism with time lags of up to 70 Myr.

ALTHOUGH plate tectonics accounts quantitatively for many geological phenomena, it does not explain-even qualitatively-large-scale continental uplift in otherwise stable areas. Migration of continents over 'hotspots' may account for uplift of continental areas that are as much as 1,000 km across¹, but is not applicable to areas such as southern Africa where hotspots of the appropriate dimensions seem to be absent. Yet heating is the only process that could bring about the necessary uplift. Heating can cause expansion as in the oceans2, or it can induce a phase change^{3,4}, which will also be accompanied by thermal expansion. Quantitative continental uplift models attribute uplift to some form of thermal anomaly in the continental asthenosphere⁵. Given a thermal anomaly, its passage through the continental lithosphere to the surface may cause effects that correspond closely to field observations, but possible causes of the anomaly-chemical and/or thermal mantle 'plumes', convection or shear heating—cannot yet be discriminated from one

The hypothesis advanced here is that a small amount of heat has been put into the base of the continental lithosphere where the past positions of ocean ridges younger than ~100 Myr, relative to South America, now lie under continents. I demonstrate that two such areas—'high Africa', and south-east Australia—have experienced strong plateau uplift some 50–60 Myr later, whereas adjacent continental areas, which lie just beyond these former ridge positions, have not. Moreover, in south-east Australia the pattern of Cenozoic volcanism lags behind in a remarkably systematic way the apparent traces of newly formed ocean floor under that continent.

Late Cenozoic uplift of Afro-Arabia

Africa is the continental part of a plate that includes much of the south-east Atlantic Ocean and the south-east Indian Ocean. Plate margins lie close to Africa only on its northern and north-east margin. A nascent plate margin may run along part of the African rift system. The African continent has undergone several uplift cycles⁶, the most recent of which is the Plio-Pleistocene uplift ('cymatogeny') that has created the present division of Africa into 'high Africa' and 'low Africa' (Fig. 1a). Significant uplift may have started as early as Miocene time (C. Hartnady, personal communication). Before the late Cenozoic, most of Africa was a continent of low relief, with an "elevation above sea level rarely more than 600 m". The Plio-Pleistocene cycle of uplift raised most of high Africa by ~1,200-1,500 m (ref. 6).

As might be expected, high Africa is associated with negative Bouguer gravity anomalies^{7.8}, whose source is attributed to variations in the level of a boundary between a deeper low density layer and an overlying high density layer in the upper mantle. This boundary can be regarded as the base of the lithosphere.

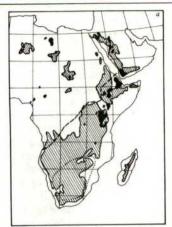

The lithosphere can also be defined by combining Bouguer anomalies with teleseismic delay times⁸, or by heat flow models⁵. Though differing in detail, all models agree that high Africa is underlain by generally thinner lithosphere than is low Africa. Thickness estimates vary considerably for low Africa: from about 250 (ref. 5), 225 (ref. 8) to 100 (ref. 7) km, with similar variations for high Africa. Recent work suggests that 'normal' continental lithosphere may be no thicker than oceanic lithosphere by that is 100 km. As a compromise, I take the lithosphere under low Africa today to be ~150 km thick, its inferred Cretaceous thickness under high Africa¹⁰.

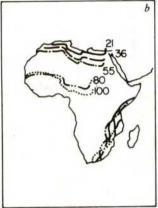

Uplift of the continent due to the physical expansion of the lithosphere should also affect the adjacent ocean floor because the boundary between high and low Africa reaches the coast. Inspection of the ocean floor bathymetry¹¹ reveals no substantial topographic anomaly across the Atlantic seaward extension of this boundary, though the effect may be negligible. Thus the topographic anomaly is largely restricted to the continent and does not appear to have its origin mainly in the thermal expansion of hot rock. This conclusion is supported by thermal calculations.

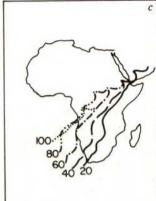

Table 1 Distance in degrees of global mean palaeomagnetic pole from geographical pole (figures not in parentheses) and distance travelled in time interval (figures in parentheses)

Continent	20	20-40	40	40-60	60	6080	80	80–100	100 Myr
Antarctica	5.7	(1.6)	4.5	(8.1)	6.1	(3.1)	3.6	(11.7)	10.2
Africa	8.2	(2.1)	9.6	(7.8)	14.2	(6.0)	20.2	(4.6)	23.8
Eurasia	6.5	(1.0)	7.2	(2.7)	8.2	(2.6)	10.3	(4.2)	11.8
North America	7.8	(1.8)	9.6	(4.3)	11.9	(5.3)	11.1	(1.0)	12.0
South America	6.0	(2.7)	5.6	(4.0)	3.3	(2.8)	6.1	(5.6)	3.2
No. of poles	89	(****)	60	,,	72	()	46	(,	52
α ₉₅	2.5		4.4		4.3		4.7		4.7

The 20 and 40 Myr data are from ref. 22; the 60, 80 and 100 Myr values use the same data base but exclude all Indian poles because of the problem of weighting poles from a rapidly moving fragment. Distances are the distance in degrees of the global mean palaeomagnetic pole calculated for the named continent from the geographical pole. The distance travelled by the pole in successive 20-Myr intervals has been calculated from successive pole positions. These can be non-zero even if the mean pole has remained at a fixed distance from the geographical pole. The global mean pole averages all known palaeomagnetic data up to 1979 from stable continental fragments on appropriate continental reconstructions the second pole for India and Australia have been omitted because these continents move substantially with respect to the poles in this time interval.

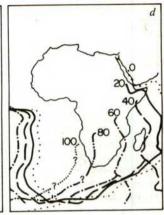

Fig. 1 a, Africa showing the distribution of Cenozoic volcanic rocks (black); the Karroo igneous rocks (within dotted line); land higher than 1,000 m (shaded); 80-Myr boundary of Africa relative to South America (dashed line). Note mutual exclusion of Karroo and Cenozoic volcanism; close similarity of northwestern edge of high Africa (essentially the 1,000-m contour) and 80 Myr boundary of Africa relative to South America. (Lambert equal area projection centred on 0° N, 15° E.) b, The past positions of Africa in the hotspot reference frame 18. There is no correlation between these positions and the boundary between high and low Africa. In b, c and d numbers are ages in Myr and cylindrical equidistant projection is used. c, Successive former positions of eastern edge of Afro-Arabia relative to South America superimposed on present-day Africa. d, Successive former positions of north-west Indian Ocean ridge under present-day Africa in past 60 Myr. The ridge positions at 80 and 100 Myr are implied by continental reconstructions, but are not known from ocean-floor anomaly data. The ridges are shown relative to a fixed South America.

For example, if it is assumed that the asthenosphere under the rift valleys is essentially at the Moho⁷, then a 150-km lithosphere under low Africa implies that much of the upper mantle under the rift valleys has been reduced in density by 26 kg m^{-3} . (Brown and Girdler⁷ adopted a thinner reference lithosphere (100 km), which requires a density contrast of 40 kg m^{-3} .) Using representative values of specific heat and thermal expansion¹², it can be shown that the heat required to bring about this density decrease by expansion alone is about $1.6 \times 10^{11} \text{ kJ m}^{-2}$ of surface area, implying an average temperature increase of $450 \, ^{\circ}\text{C}$, which is absurdly high.

Similarly improbable values are obtained from heat flow calculations. For example, the temperature increase at the base of a 150-km thick lithosphere needed to cause 1,200 m of uplift is about 1,000 °C (ref. 5), which is far too high. Alternatively, 1,200 m of uplift will take at least 100 Myr (ref. 5) if the heat flux at the base of a 150-km plate is increased by ~94 mW m⁻¹, about twice the average continental heat flow. All these thermal models require the crust under southern Africa to have partially melted, creating abundant magmatism in an area that is notably free from it. Despite their success in explaining ocean-floor subsidence², conduction uplift models cannot account for rapid plateau uplift of continents.

Phase change?

I suggest that the uplift of high Africa is most reasonably interpreted as a phase change. I assume the phase change to be analogous to the basalt/eclogite phase change and to occur at the Moho itself, taken initially at 40 km depth. The density change is from a relative density of 3.4 to 3.0. To create 1.2 km of uplift, 9 km of eclogite will have been converted to 10.2 km of 'basalt'. An analogous reaction is that of quartz eclogite to granulite.

Both reactions can be idealized, the first as (in moles)

- 3 Forsterite + 3 Diopside + 5 Plagioclase [An₆₀Ab₄₀]
 - = 3 Garnet + 5 Omphacite [=Jd₄₀Di₆₀]+2 Quartz

and the second as:

- 2 Enstatite + 2 Plagioclase + Diopside
 - = Garnet + 2 Omphacite + 2 Quartz

The enthalpy change for the quartz eclogite to granulite reaction can be estimated from thermochemical data at 10⁵ Pa (refs 13, 14) and extrapolated to high pressures. It probably lies between

 -24.7 kJ kg^{-1} at 10^9 Pa and -46.0 kJ kg^{-1} at $1.5 \times 10^9 \text{ Pa}$. The enthalpy change for eclogite to 'basalt' at atmospheric pressures is very similar to that of quartz eclogite to granulite and is assumed to have a similar range at high pressures. These values probably have an uncertainty of 8 kJ kg⁻¹. For simplicity I adopt a value of 46 kJ kg⁻¹. The total heat required to convert 9 km of 'eclogite' to 10.2 km of basalt is 1.4×104 kJ m⁻² of crosssection. Thus the thermal energy needed for uplift due to a phase change is 100 times more effective than the energy needed for thermal uplift. The heat needed for a phase change uplift is equivalent to increasing the average temperature of the lithosphere by 4 °C accompanied by 11 m of uplift. Such a small uplift cannot yet be detected in the residual depth anomalies of the adjacent ocean-floor. However, unlike thermal expansion, the active position of a phase change will be limited to a relatively narrow zone, rather than affecting all rocks, whatever their nature.

The numerous Mesozoic eclogite-bearing kimberlite pipes of southern Africa¹⁵ demonstrate the presence of eclogite in Mesozoic time in the upper mantle of southern Africa. Those eclogites containing diamonds come from much deeper levels, but others probably lay in the depth range of a possible phase change. The grain textures in some of the kimberlite inclusions show that during the Cretaceous there was a marked textural discontinuity at ~150 km depth where the temperature is estimated to have been ~1,200 °C (ref. 10). This textural discontinuity implies a rapid stress drop at this level and can be taken as marking the Cretaceous lithosphere–asthenosphere boundary. Thus 70 Myr or more ago, eclogite was present in the upper mantle of southern Africa, and the lithosphere was

Table 2 Instantaneous absolute rotations of the American plate for three different models¹⁹

Model parameters	Lat.	Long.	Rotation rate (10 ⁻⁷ deg yr ⁻¹)
B4: continents have 3 times more drag than oceans	-62.0	-108.2	1.65
C4: drag under plates; slab pull at oceanic and continental	-46.5	-89.5	1.72
subduction zones D1: maximum pull by slabs and plate drag	-86.9	-61.3	0.89

150 km thick. How much eclogite was present and where it was distributed are not known, but similar kimberlite diatremes occur in the Colorado Plateau and in south-east Australia^{16,17}. In both these regions the mantle in the 40–70-km depth range might have contained up to one-third eclogite and other high pressure assemblages capable of inverting to lower density rocks^{16,17}.

The thermal time constant due to temperature changes of the continental lithosphere is ~63 Myr (ref. 9). For a phase change at the Moho, the time constant for heat originating at the base of the lithosphere is smaller. The minimum extra heat flux required for a phase change is the heat needed divided by the time available, or 4.6 mW m⁻². This heat is the minimum extra heat flux required above the value prevailing just before 10 Myr, because 10 Myr or so ago the latest phase of African uplift was just about to start. It would be less if uplift started earlier (C. Hartnady, personal communication). Clearly, a phase change overcomes the temperature problem, but it would not be expected to give such a rapid uplift pulse as is inferred from the geomorphology. Presumably, the sharpness of this uplift is caused by simultaneous thermal thinning of the lithosphere by the heat pulse as it moves upward⁵. Thus we are looking for a thermal pulse originating below Africa some time ~70 Myr ago, that probably thinned the lithosphere-because the isotherms would have been raised—and has augmented the previous heat flux at ~ 40 km by at least 4.6 mW m⁻², or about one-tenth of the average continental heat flow.

The increase in surface heat flow will be much less because the phase change itself will initially absorb much of the heat. The increase in temperature, as opposed to the minimum increase in heat flux, is difficult to estimate. However, a maximum temperature increase of 100 °C is suggested.

South America as a reference frame

To investigate this problem further we need a reference frame. The hotspot reference frame¹⁸ shows no relationship between possible hotspots or other hot areas and areas of uplift in southern Africa (Fig. 1b), presumably because hotspots do not cause plateau uplift. The hotspot reference frame is therefore rejected. Absolute reference frames are those in which there is no net rotation of the lithosphere¹⁹. Palaeomagnetic data suggest that for the past 50 Myr the equatorial components of any net finite rotation of the lithosphere relative to the mean global palaeomagnetic pole are perhaps as small as 2° (refs 20, 21). Because of the longitude indeterminacy, palaeomagnetic data cannot be used to find the polar component of any such rotation.

Nevertheless, I take here as reference frame that continent which has moved least relative to the global palaeomagnetic pole in the past 100 Myr, realizing that a finite rotation of arbitrary magnitude about the pole can be superimposed at any time on such a continent without being palaeomagnetically detectable. The continent that has moved least relative to the global palaeomagnetic pole is South America (Table 1)²². That

Table 3 Angular differences between instantaneous 'absolute' rotation poles and finite rotation poles for 55-Myr reconstruction

Fixed continent	Continent moved	Differences (deg) between finite rotation pole and instantaneous 'absolute' rotation pole			
			Model ¹⁹		
		B4	C4	D1	
Antarctica	Africa	37.8	32.7	51.9	
Eurasia		47.6	47.3	41.2	
North America		36.6	41.9	18.6	
South America		15.5	20.3	4.3	
Antarctica	Australia	22.8	24.9	24.0	
Eurasia		19.6	21.8	20.9	
North America		6.5	11.1	4.3	
South America		7.5	4.1	11.3	

is, its average distance from the pole and the average distance moved during successive intervals are smaller than that for any other major continent.

Independent support for taking South America as a reasonable approximation to an absolute reference frame is provided by absolute motion studies¹⁹ (Table 2). Except for the Caribbean plate, in five out of eight models¹⁹ examined, the American plate (combining North and South America into one plate) has the smallest r.m.s. absolute velocity¹⁹. South America alone would have the smallest r.m.s. absolute velocity of all the larger plates because it generally lies close to the American rotation pole (Table 2). Inspection of the velocity field for model A3 of Solomon et al.'s¹⁹ also shows the very small linear velocities of South America.

South America was adopted as a reference frame because it approximates to the present absolute reference frame, and the rotation poles support this choice. Lithospheric thickening and subduction slab pull seem to account for most of the driving forces on a plate²³. In the case of the Australian and African plates the gross relative geometry of ridges and subduction zones has not changed much in the past 55 Myr. Before then, Australia was part of the Antarctic plate and a very different plate geometry existed^{21,24}. Therefore, we might expect that, to a first approximation, the instantaneous rotation poles in the absolute reference frame are not far from the finite poles for the period 0–55 Myr. We know the finite poles relative to the continental plates²². The plate that moves least relative to the absolute reference frame is likely to be that plate with respect to which the calculated finite rotation poles of Australia and Africa are closest to their present-day instantaneous-absolute rotation poles.

The three absolute motion models¹⁹ closest to Harper's successful driving force model^{24,25} were chosen (B4, C4 and D1)¹⁹ and the results compared (Table 3). (D1 gives too high a net rotation of the lithosphere, but is retained for interest.) Clearly, the assumed finite pole of Australia in the absolute reference frame is equally close to the actual finite rotation pole in a reference frame fixed to either of the Americas. But only South America gives an actual finite rotation pole which is close to the assumed finite absolute reference frame pole for Africa.

During the period 100-0 Myr, Africa has rotated anticlockwise relative to South America (Fig. 1c, d). In particular, those areas affected by plateau uplift now overlie or have passed across the former positions of the oceanic ridges that separated Madagascar and India from Africa in the same period. There is, in fact, a remarkable coincidence between the area of high Africa and the area swept out by these oceanic ridges in a reference frame fixed to South America (Fig. 1a, c, d). The high-low Africa boundary essentially coincides with the trace of the southeastern edge of Africa at 80 or 60 Myr on presentday Africa (Fig. 1c, d). The hypothesis is that a thermal pulse, originating in the underlying asthenosphere at ~70 Myr, caused uplift about 50-60 Myr later. Imposing the small rotation needed to put South America into the present absolute reference frame (Table 2), assuming it has been unaltered for 70 Myr, would not alter this visual correlation between uplifted areas and former ridge positions.

Late Cenozoic uplift and volcanism of south-east Australia

I test this hypothesis by examining the uplift history of a second otherwise stable continent that also overrode former oceanic ridge positions in a South America reference frame: south-east Australia. Relative to South America, south-east Australia moved onto the former ridge position in the Tasman Sea shortly after it had opened between 76 and 56 Myr (refs 26, 27). If the Australian lithosphere is similar to Africa, I expect strong uplift beginning ~16 Myr ago.

The south-east Australian highlands form a 300-km wide tract rising to over 1,000 m above sea level, whose western boundary is roughly parallel to the trace of the western edge

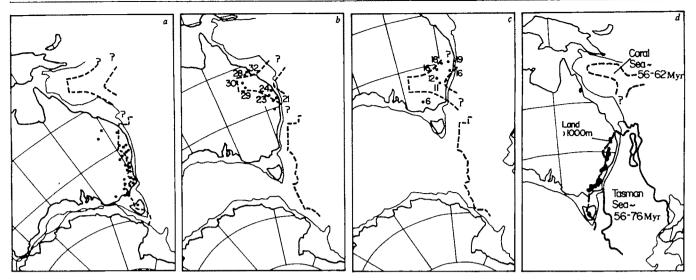

Fig. 2 a, Australia relative to South America at 55 Myr. The thick dashed lines show the approximate positions of the edges of Tasman Sea and the Coral Sea generated earlier relative to South America. •, Central volcanoes, ages in Myr (ref. 34), whose activity reached a peak in 55-34 Myr. Note the coincidence between these volcanoes and the position of the Tasman Sea ridge in a reference frame fixed to South America, with a time-lag of perhaps 20-30 Myr. b, As a but at 40 Myr. Note how the inferred position of the Coral Sea ocean floor at 40 Myr in a reference frame fixed to South America coincides with lava field provinces formed some 13 Myr later. In b and c, numbers are ages of alkaline central volcanoes in Myr (ref. 34). c, As a but at 20 Myr. Note how the inferred position of the Coral Sea ridge positions fixed to South America at 20 Myr coincides with the lava field provinces formed some 6 Myr later d, Present-day map showing Australia; the approximate age and distribution of ocean floor in the Coral Sea and Tasman Sea; the trace of the western edge of Tasman Sea from a and land over 1,000 m (black areas). Note the approximate coincidence of the highlands uplifted in Oligocene or later time, with the trace of the western edge of the Tasman Sea of early Tertiary age fixed to South America. a, b, c Are the same windows on Lambert equal-area maps in which South America is fixed; d is a window on a present-day Lambert equal-area map.

of the Tasman Sea at 76 Myr under Australia at 55 Myr, both in a South American fixed reference frame (Fig. 2d). Most studies conclude that at least in the south-east 80% or more of the uplift has taken place since the Oligocene (more recently than 22 Myr)²⁸⁻³¹, though some authors believe it to be much older³², or to have started earlier and to have been constant with time³³. Neighbouring areas have not been affected by so marked an uplift. Thus the area affected by uplift and the consensus of geomorphic interpretations fit well with the hypothesis.

Unlike high Africa, the south-east Australian highlands are closely linked to volcanism: a linear zone of basaltic lava fields is roughly coincident with the highland crest^{34,35} (Fig. 2a). Where data allow interpretation, a westward component is seen in the migration direction of this volcanism³⁴, which is expected if the heat sources are fixed in a South American reference frame.

At \sim 55 Myr, Australia started to move northwards relative to South America at \sim 53 mm yr⁻¹, eventually bringing the southeastern highlands region onto the former positions of the ridges in the Coral Sea, which was also relatively young³⁶ (Fig. 2b, c). A suite of alkalic central volcanoes formed, starting in the north at \sim 30 Myr, and migrating south to reach Victoria \sim 6 Myr ago, with an average migration rate of 66 ± 5 mm yr⁻¹ (ref. 34) (Fig. 2c). Like the basaltic lava fields, there is a similar time lag between the arrival of the affected parts of the highlands over the Coral Sea ridge positions and subsequent alkaline volcanism (Fig. 2b, c).

The similarity in timing between the lava field volcanism and the opening of the Tasman Sea has been noted previously^{34,35}, but no precise cause has been proposed. Likewise, the "remarkable migration of eruptive centres southwards (66 mm yr⁻¹) with time at a rate similar to the drift of Australia northward from Antarctica (56 mm yr⁻¹)" has been related to possible plumes and/or hotspots in the underlying asthenosphere^{34,35}. However, the northward migration of Australia relative to South America is at a similar rate, 53 mm yr⁻¹.

I propose that instead of asthenospheric plumes or hotspots causing magmatism, that the magma source originally lay within the Australian lithosphere. As a heat pulse moved upwards from the former positions of the Tasman and Coral Sea ridges,

the lithosphere thinned, eventually bringing the source region into the asthenosphere. As there seems to be a 20-Myr time lag between overriding of the continent and the onset of volcanism, I assume that the source originally lay well above the base of the lithosphere. Taking 65 Myr as the time constant for conductive heat transport for the whole continental lithosphere and a thickness of ~ 150 km, I estimate that a 20-Myr time lag probably implies a source depth of $\sim 70-110$ km below the surface.

The zone causing uplift some 60 Myr after Australia overrode the former positions of the western edge of the Tasman Sea must lie at much shallower levels, presumably in a zone capable of a phase change in the uppermost mantle. South-east Australian kimberlites, mostly of Jurassic age, include eclogites and other inclusions¹⁷. Refraction seismic lines show too that the present-day lithosphere in south-east Australia has a broad transition from crustal to mantle velocities, which could correspond to a zone of phase change³⁷.

Discussion

Provided that the former ridge positions also mark the locations of slightly hotter asthenosphere, the physical requirements of a phase change origin for African uplift lead to conditions that can be satisfied by the kinematics in a South American reference frame. I postulate that during the interval 80-40 Myr or so. what is now high Africa moved onto asthenosphere that had risen towards the surface as a direct result of Indian Ocean spreading. This asthenosphere was slightly hotter than the original asthenosphere under high Africa and created a heat pulse at the base of the African plate, which was too small to have a significant effect on the depth of the ocean floor, but was large enough to cause a phase change (or phase changes) in the uppermost 30 km or so of the continental mantle some 40-80 Myr later. Although three-dimensional mantle circulation models do not embody the complexities found in real-, cross-sections through such a circulation model in the present absolute reference frame at the present-day Carlsberg Ridge^{38,39} show the situation envisaged: deeper, and therefore hotter, asthenosphere rising up to replace preexisting asthenosphere under the edge of the African plate, which the plate will eventually cover. In the absolute reference frame the ridges must move relative to their immediately underlying asthenospheric sources 15

What is not clear is why the past positions of the ridges in the approximate absolute reference frame provided by South America seem to match the areas of uplift so well. One possibility is that because asthenospheric sources are probably vertically extensive^{38,39} and have horizontal velocities much less than the overlying plates^{38–40}, the asthenospheric zone extending from vertically above the deep source of a new ridge to the present position of the ridge may all have become hotter than it was before ridge creation. If so, this increased temperature could provide the heat needed for the phase change.

In detail, this model must be modified. For example, the uplift of southern Africa has been treated as a uniform vertical uplift simultaneously affecting all of high Africa, yet it is quite clear from Fig. 1c, d that we would expect a wave of uplift to have moved across high Africa starting in the east, and taking a geologically significant time to reach the west. This problem will not be discussed here in detail because part of its solution depends on considering still earlier phases of uplift probably resulting from the breakup of Gondwanaland. Nevertheless, it is worth noting that there is a distinct structural and topographic

asymmetry to southern Africa. The Cenozoic Kalahari basin lies in the western half of southern Africa, while the eastern half consists primarily of Precambrian rocks: during much of Cenozoic time, the eastern half of southern Africa has been structurally raised relative to the western half. In addition, the topography is markedly asymmetric: the highest parts of southern Africa are in Lesotho, very close to the eastern margin. Here, and nowhere else, the topography rises to well over 3 km. This structural and topographic asymmetry is what would be expected from a more detailed application of the model. The same mechanism is envisaged for the uplift of south-east Australia, where the expected topographic asymmetry is quite clear.

All these speculations can be tested by better data from the uplift of land surfaces, high-pressure petrology and threedimensional mantle flow models.

I thank P. England for providing a heat calculation programme and T. Holland for working out the likely values of the heats of reaction involved, also M. J. Bickle, E. Leitch, L. Nicolaysen, S. Richardson, F. J. Vine and N. H. Woodcock for comments and criticisms. Adele Prowse drew the figures. The production of the diagrams was greatly aided by the mapmaking system developed under a grant from the NERC GR3/2277. Cambridge Earth Sciences contribution no. 253.

Isolation and preliminary characterization of a human transforming gene from T24 bladder carcinoma cells

Mitchell Goldfarb, Kenji Shimizu, Manuel Perucho & Michael Wigler

Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, USA

DNA from T24, a cell line derived from a human bladder carcinoma, can induce the morphological transformation of NIH 3T3 cells. Using techniques of gene rescue to clone the gene responsible for this transformation, we have found that it is human in origin, <5 kilobase pairs in size and is homologous to a 1,100-base polyadenylated RNA species found in T24 and HeLa cells. Blot analysis indicates extensive restriction endonuclease polymorphism near this gene in human DNAs.

THE progression of a cell lineage from normalcy to malignancy may involve the mutation or activation of one or more genes. The genomes of retroviruses contain candidates for such 'oncogenes'. Certain retroviruses capable of inducing neoplasia in vivo and cell transformation in vitro contain transduced cellular genes which entirely encode the oncogenic proteins of these viruses^{1,2}. If these or other oncogenes are expressed in tumours of viral or nonviral origin, the introduction of these

genes into cultured cells might transform the recipients and render them tumorigenic. Indeed, DNA from some chemically transformed mouse cells can morphologically transform NIH 3T3 mouse fibroblasts following DNA-mediated gene transfer³. More recently, it has been reported that DNA from certain human tumour cell lines can also morphologically transform NIH 3T3 cells^{4,5}. We have detected transforming activity in DNA from 5 of 21 human tumour cell lines6; the resulting NIH 3T3 transformed cells are tumorigenic in nude mice⁴⁻⁶. Human DNA from one colon and two lung carcinoma cell lines appear to contain the same or highly related transforming elements, while DNA from a bladder carcinoma and from a neuroblastoma cell line each contain different transforming elements⁶. These transforming genes may have played a critical part in the origins of the tumours from which these cell lines derive. Here, we report the molecular cloning and preliminary characterization of the transforming gene from the human bladder carcinoma cell line, T24 (ref. 7).

Strategy of gene isolation

In principle, a gene can be isolated whenever its transfer into an appropriate host results in the stable acquisition of a selectable phenotype, using either 'search' or 'rescue' strategies. In the former, a complete genomic library is constructed in plasmids, phage or other cloning vehicles, and individual members of the library are screened by DNA-mediated gene transfer. This approach has been used successfully to isolate genes from lower organisms⁸. The rescue strategy entails cleaving DNA from cells containing the gene with a restriction endonuclease and then ligating this DNA to a defined 'marker' sequence. The ligated DNA is then used in gene transfer experiments, ultimately yielding a cell bearing the transferred gene linked to the marker sequence. The gene is isolated by one of several means on the basis of its association with the marker. The chicken thymidine kinase (tk) and hamster adenine phos-

DNA (total concentration 30 μg ml⁻¹) was precipitated with calcium phosphate and 1 ml of suspension was applied to 10⁶ NIH 3T3 cells in a 10-cm culture dish, as previously described¹². Restriction endonuclease-digested T24 and T24-a2 DNAs were mixed in a 1:2 ratio with uncleaved NIH 3T3 DNA before precipitation; samples of phage and plasmid DNAs were added to 30 μg NIH 3T3 DNA before precipitation. Cellular DNAs were prepared by SDS-proteinase K lysis and phenol/chloroform extraction⁶. Phage DNAs were prepared from CsCl gradient-purified virions¹⁸ and plasmid DNA was purified from saturated culture of bacteria¹⁹. a Shows the NIH 3T3 focus-forming activity of DNAs from four independent suppressor-containing phages; b compares the focus-forming activity of λsup2.9 DNA and pBR322 subclone pTB-1 DNA, and compares the restriction endonuclease sensitivity profile of the activity in λsup2.9 DNA with the previously reported activities in T24 and T24-a2 cellular DNAs. NT, not tested.

* Value in parentheses is the calculated frequency of focus induction per transforming gene equivalent. In these calculations, we have taken the molecular weight of the human haploid genome to be 1.5×10^{12} .

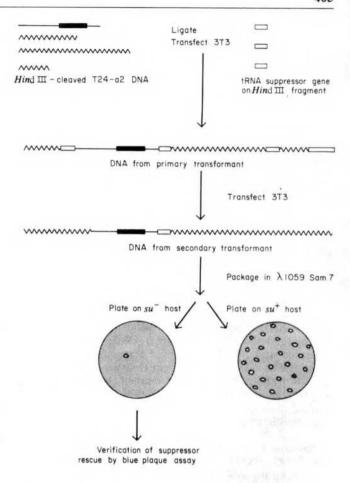

Fig. 1 Suppressor rescue of the T24 transforming activity. A recombinant DNA plasmid, pK-7, containing a supF tRNA amber suppressor gene was given by Dr U. RajBhandary. The suppressor gene was further subcloned into pBR322 plasmid (K.S. et al., in preparation). This subclone, pK-5, was cleaved with restriction endonuclease HindIII, and the 1.1-kbp suppressor DNA fragment was purified by gel electrophoresis and binding to glass powder²⁰ . T24-a2 is a transformed NIH 3T3 cell line derived from transfection of NIH 3T3 cells with T24 DNA. HindIII-cleaved T24-a2 DNA was ligated in fourfold mass excess to suppressor fragment DNA with T4 DNA ligase (New England Biolabs) at a total DNA concentration of 250 ug ml . Ligated DNA was mixed with a twofold mass excess of NIH 3T3 DNA and transfected to NIH 3T3 cells by methods described elsewhere 12. This ligated DNA induced foci at a threefold lower efficiency than native T24-a2 DNA in the absence of suppressor. Resulting transformed cells were cultured from individually picked foci. DNA from these cells should contain some supF sequences closely linked to the transforming element, but most supF genes, introduced by co-transfer, will not be closely linked. These DNAs were transfected again to NIH 3T3 cells, yielding secondary foci bearing only closely linked supF sequences. DNA from six secondary foci were partially digested with restriction endonuclease Sau3A, and 10-20-kbp fragments were purified by centrifuging 150 µg DNA through a 15-40% (w/v) sucrose gradient (in 100 mM NaCl, 10 mM Tris pH 7.4, 1 mM EDTA) at 23,000 r.p.m. in a Beckman SW27 rotor for 24 h at 20 °C. From the six individual size-selected DNA preparations, a total of 5.3 µg DNA fragments (250 µg ml⁻¹) were ligated to a twofold mass excess of gel-purified phage DNA arms generated by cleavage of λ1059Sam7 DNA with endonuclease BamHI. λ1059Sam7 was derived from in vivo recombination between \$1059 and \$Sam7 (K.S. et al., in preparation). Chimaeric phage DNA molecules were packaged into virions by a standard procedure¹⁵. A total of 8.4×10⁶ phage particles were generated by packaging, as measured by titration on E. coli BNN45 supEsupF cells. These phages were plated onto E. coli KS624 sup0(r-, m+) cells (K.S. et al., in preparation). Thirty-four individual plaques which arose were picked and the phages screened for the presence of amber suppressor by spotting on to lawns of $lacZ^{am}$ sup⁰ cells in the presence of lacZ inducer isopropyl thiogalactoside and indicator substrate, Xgal (5-bromo-4-chloro-3-indoyl-\$\beta-D-galactoside; ref. 21). Suppressor-bearing phage suppressed the $lacZ^{am}$ mutation, generating a blue plaque by β -galactosidase cleavage of Xgal. By this procedure, we isolated four suppressor-bearing phages. In the upper part of the figure, - denotes human DNA sequences; w. mouse DNA sequences; ■, T24 transforming gene; and □, tRNA supF gene.

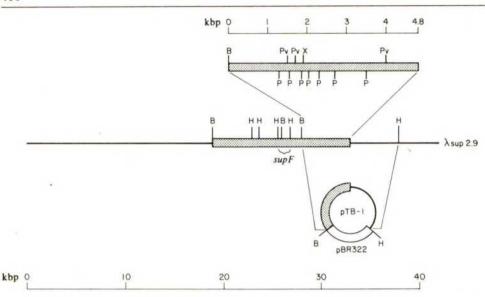

Fig. 2 Restriction endonuclease cleavage man of Asun2.9 and nTB-1. The figure shows the restriction map of DNA from the recombinant bacteriophage Asup2.9 which was active in transformation assays. Phage arms are denoted by a thin line, and the 14-kbp DNA insert by a shaded box. The suppressor DNA fragment' is marked supF. Below is shown the circular map of pTB-1, with the BamHI/HindIII fragment Asup2.9 cloned into pBR322, denoted by an open box. Above is shown a more detailed restricted map of the cloned T24 bladder carcinoma transforming sequences. The cluster of PstI sites were mapped by the method of Smith and Birnsteil²². There are no EcoRI, HindIII or BglII sites in this sequence. B, BamHI; H, HindIII; P, PstI; Pv, PvuII.

phoribosyl transferase genes were isolated using the Escherichia coli plasmid pBR322 as the marker sequence.

In this study, we have adopted a modified rescue strategy using an E. coli tRNA amber suppressor gene, supF, as marker. Details of this method will be published elsewhere (K.S. et al., in preparation) but the scheme is outlined in Fig. 1. From pK-7, a plasmid which contains supF, we constructed a new plasmid from which the supF gene could be recovered as a 1.1-kilobase pair (kbp) DNA fragment following cleavage with HindIII. This suppressor DNA fragment was ligated in equimolar ratio to HindIII-cleaved DNA from T24-a2, an NIH 3T3 transformant containing the T24 transforming gene. HindIII cleavage does not affect the transforming activity of either T24 or T24a2 DNA (see Table 1). We used T24-a2 DNA as our gene source because it has a higher specific activity of transformation than T24 DNA. Ligated DNA was mixed with a twofold mass excess of NIH 3T3 cellular DNA and added as a calcium phosphate precipitate to NIH 3T3 cells11,12. Morphologically transformed foci were picked 2 weeks later and grown into mass culture. Blot hybridization analysis indicated that cells from these foci contained multiple copies of the bacterial tRNA gene. Presumably, at least one of these copies directly flanked the transforming gene while the others did not. Therefore, DNA from these transformants was again used for gene transfer to generate new foci. DNA from a few of the resulting foci retained one or two copies of the tRNA gene, and these DNAs were used in subsequent experiments.

To clone the tRNA suppressor gene and its flanking sequences, we used a biological selection based on the ability of the cloned tRNA gene to suppress amber mutations when incorporated into a mutant of bacterophage A. We introduced by molecular recombination an amber mutation (Sam7)13 into the lysis gene of λ1059, a cloning vehicle which accepts 7-18-kbp DNA fragments having GATC3'OH cohesive ends14. The resulting phage, \$1059Sam7, required a supF host to complete a lytic cycle. DNA from transformed animal cells containing one to two copies of supF were partially digested with restriction endonuclease Sau3A and ligated to purified arms of λ1059Sam7 DNA generated by BamHI cleavage. The ligated DNAs were packaged into phage particles15 and plated onto sup⁰ and supF hosts. Phages which grew on sup⁰ hosts were further identified as supF-containing by their ability to convert a lacZ^{am} sup⁰ host to lacZ⁺. From such a screening process, we obtained four independent supF phage recombinants.

Cloned sequences transform NIH 3T3 cells

DNA from the four *supF* phages were mixed with NIH 3T3 carrier DNA and assayed for the ability to transform NIH 3T3 cells. As shown in Table 1, \(\lambda\)sup 2.9 DNA induced transformed

foci at an efficiency of ~ 300 foci per μg . The three other phage DNAs were inactive in transformation. As a first step in verifying whether the $\lambda \sup 2.9$ transforming activity is the same as that in T24 DNA, the activity of $\lambda \sup 2.9$ cleaved with restriction endonucleases was compared with similarly cleaved T24 DNA. Table 1 shows that the transforming activity of $\lambda \sup 2.9$ DNA is destroyed by cleavage with XbaI but not with BamHI, BgIII, EcoRI or HindIII. The same is true for T24 DNA.

To localize the transforming sequences of $\lambda \sup 2.9$, we subcloned restriction fragments of $\lambda \sup 2.9$ into pBR322. Cleavage

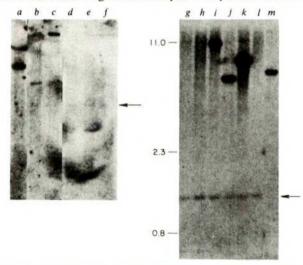

Fig. 3 Hybridization of pTB-1 DNA and one of its restriction endonuclease fragments to filter-blotted DNA from transformed NIH 3T3 cells. DNAs from NIH 3T3 cells, transformed NIH 3T3 and T24 cells were cleaved with either HindIII or BamHI restriction endonuclease. Digested DNAs (6 µg of each) were electrophoresed through 1.0% agarose gels and transferred to nitrocellulose filters as previously described 16. Blotted DNAs were hybridized with nick-translated 32P-DNA from either pTB-1 or the 800-bp PstI fragment of pTB-1. Hybridizations were performed at 74 °C for 16 h in 6× SSC, $1 \times$ Denhardt's solution and 20 µg ml⁻¹ denatured salmon sperm DNA²³. *Hin*dIII-cleaved cellular DNAs probed with pTB-1 ³²P-DNA (20 ng ml⁻¹) (a-f); BamHI-cleaved DNAs probed with the PstI fragment 32P-DNA (g-m). d, l, DNA from NIH 3T3. Secondary transformants of NIH 3T3 transformed with T24 DNA: T24-a1-3 (c, k); T24-a2-1 (a, j); T24-a5-4 (b, i). e, h, Secondary transformant of NIH 3T3 transformed with DNA from Calu-1, a human lung carcinoma cell line. f, g, Primary transformant of NIH 3T3 transformed with DNA from SK-N-SH, a human neuroblastoma cell line. m, T24. Hybridization of probe to HindIII-cleaved Asup2.9 DNA and PvuII- or PstI-cleaved pTB-1 DNA provided molecular weight standards as indicated (in kilobase pairs).

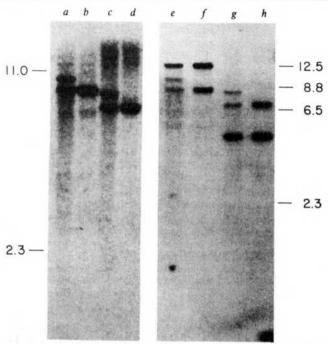

Fig. 4 Hybridization of pTB-1 DNA and its 800-bp PstI fragment to filter-blotted DNA from T24 cells and human placenta. Human placental DNA (given by J. Fiddes) and T24 DNA were cleaved with restriction endonucleases, electrophoresed through 1.0% agarose gels and transferred to nitrocellulose filters. Blotted DNAs were hybridized with 20 ng ml⁻¹ pTB-1 ³²P-DNA (e-h) or 2 ng ml⁻¹ gel-purified, ³²P-labelled 800-bp PstI pTB-1 DNA fragment (a-d). BgIII-cleaved placenta DNA (a, e); BgIII T24 (b, f); BamHI placenta (c, g); BamHI T24 (d, h). Hybridization of probes to XbaI- or HindIII-cleaved Asup2.9 DNA and PvuII-cleaved pTB-1 DNA provided molecular weight standards (in kilobase pairs).

of Asup2.9 DNA with BamH1 and HindIII generates seven restriction fragments, five of which contain heterogeneous ends (Fig. 2). These were then inserted between the BamHI and HindIII sites of pBR322 DNA. When individual plasmid subclones were tested for their ability to transform NIH 3T3 cells, only subclone pTB-1 had transforming activity, pTB-1 DNA contains a 9.8-kbp inserted sequence spanning the rightmost BamHI site in Asup2.9 to the HindIII site within the right arm of the phage DNA. As this region contains 5.0 kbp of λ DNA sequences, the transforming activity in pTB-1 is encoded in a transforming sequence no larger than 4.8 kbp. A more detailed restriction endonuclease map of this 4.8-kbp region is shown at the top of Fig. 2. The specific transforming activity of pTB-1 was higher than that of Asup2.9, but was consistently lower in a series of experiments than the specific activity calculated for the chromosomal gene in T24, assuming the gene is present in T24 as a single copy (for example, see Table 1). This agrees with our previous results for clones of the chicken tk gene which transfer at reduced efficiencies compared with the chromosomal gene9.

pTB-1 contains transforming sequences of T24 bladder carcinoma cells

Hybridization studies provide further evidence that we have cloned transforming sequences from the T24 bladder carcinoma cell line. DNAs from NIH 3T3 cells, NIH 3T3 cells transformed with T24 DNA and NIH 3T3 cells transformed with DNA from other human tumour cell lines were digested with *HindIII*, electrophoresed through agarose gels, and transferred to nitrocellulose filters by the procedure of Southern to nitrocellulose filters by the procedure of Southern transformants resulting from two cycles of transfection of tumour cell DNA through NIH 3T3 cells. The filters were hybridized with nick-translated 32P-labelled pTB-1 DNA. Figure 3 shows that pTB-1

sequences hybridize weakly to a specific HindIII fragment in DNA from NIH 3T3 cells and all its transformants (indicated by arrow at right of lane f). pTB-1 also hybridizes weakly to specific restriction fragments of normal rat cellular DNA (data not shown). In addition to these interspecies homologies, pTB-1 hybridizes strongly to a single HindIII fragment in each of three independent secondary transformants of T24 (Fig. 3, lanes a-c), while NIH 3T3 DNA shows no additional hybridization (lane d). We conclude that pTB-1 contains the transforming sequences present in T24 DNA. DNA from an NIH 3T3 secondary transformant derived from human lung carcinoma, Calu-1 DNA (Fig. 3, lane e) and DNA from an NIH 3T3 primary transformant derived from human neuroblastoma, SK-N-SH DNA (lane f), also lack additional sequences homologous to pTB-1, demonstrating that the transforming element in T24 differs from that in Calu-1 and SK-N-SH cells. This conclusion is consistent with our previous findings6.

Human placental DNA contains sequences homologous to the T24 transforming gene

If the transforming activity in T24 DNA arose by the acquisition of exogenous (for example, viral) genetic information, then

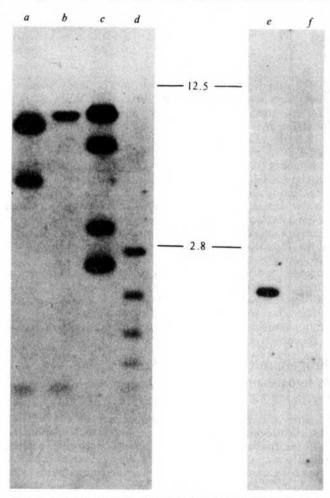

Fig. 5 Hybridization of pTB-1 DNA to filter-blotted T24 and pTB-1 DNAs cleaved with restriction endonucleases. T24 cellular DNA (6 μg) and pTB-1 (50 pg) were cleaved with restriction endonucleases, electrophoresed through a 1.0% agarose gel, then transferred to a nitrocellulose filter. pTB-1 DNA was cleaved with PstI (a) and PvuII (c); T24 DNA was cleaved with PstI (b) and PvuII (d). These blotted DNAs were hybridized to total pTB-1 ³²P-DNA (20 ng ml⁻¹). 20 pg of the 1.9-kb purified fragment of BamHI/XbaI-cleaved pTB-1 (e) and T24 DNA cleaved with BamHI/XbaI (f) were hybridized to the ³²P-labelled 1.9-kbp BamHI/XbaI pTB-1 fragment (5 ng ml⁻¹). Hybridization of probe to XbaI-cleaved Asup2.9 DNA provided molecular weight standards (in kilobase pairs).

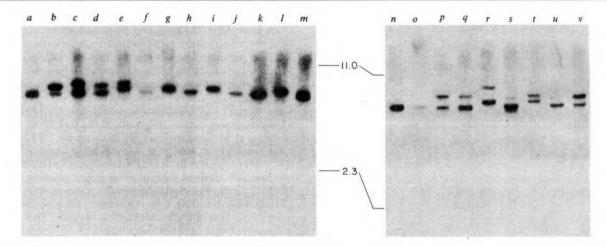

Fig. 6 Hybridization of the 800-bp PstI fragment of pTB-1 DNA to filter-blotted DNAs from human tumours and tumour cell lines. Human tumour cell lines were given by J. Fogh. Human tumours were obtained from the NCI Tumor Repository. DNAs from human tumours and tumour cell lines were cleaved with BamHI restriction endonuclease, electrophoresed through 1% agarose gels and then transferred to nitrocellulose filters. Blotted DNAs were hybridized to 2 ng ml⁻¹ gel-purified ³²P-labelled 800-bp PstI pTB-1 DNA fragment. DNAs from tumour cell lines: a, epidermis RPMI 2650; b, colon HT-29; c, cervix C4II; d, glial cell T98; e, osteosarcoma 8387; f, breast MCF-7; g, cervix HeLa; h, bladder T24; i, melanoma RPMI 4445; j, fibrosarcoma SW594; k, bladder 575A; l, bladder 496P; m, bladder TCCsup; u, pancreas Capan-1; and v, bladder VM-CUB-2. DNAs from human tumours: n, colon 031-10687; o, lung 031-9337; p, lung 031-11971; q, colon 76-640; r, lung 031-31317; s, colon 021-769; and t, lung 76-126. Hybridization of the probe to HindIII-cleaved λsup2.9 DNA and PvuII-cleaved pTB-1 DNA provided molecular weight standards (indicated in kilobase pairs).

pTB-1 would probably hybridize to a T24 DNA sequence absent from human placenta DNA. To examine this possibility, T24 and human placenta DNAs were cleaved with either BamHI or BglII restriction endonuclease, and digested DNAs were analysed by filter blot hybridization, using 32P-labelled pTB-1 DNA as probe. Figure 4 shows that pTB-1 hybridizes to 8- and 12-kbp BglII fragments (lane f) and to 5.0- and 6.8-kbp BamHI fragments (lane h) from T24 DNA. The probe hybridizes to BglII (lane e) and BamHI fragments (lane g) of identical size in human placental DNA. We also observed that T24 and human placental DNAs have similarly sized EcoRI or HindIII fragments homologous to pTB-1 (data not shown). As all the T24 DNA restriction fragments homologous to pTB-1 have similarly sized counterparts in placental DNA, we conclude that the T24 transforming gene originated from human genetic information without the gross rearrangements of 'normal' DNA sequences. The fact that additional 9.5-kbp BglII and 7.9-kbp BamHI fragments homologous to pTB-1 are present in placental DNA but absent from T24 DNA, we attribute to genetic polymorphism (see below).

Subgenomic fragments of pTB-1 suitable as hybridization probes for the T24 transforming gene

We wished to use pTB-1 as a hybridization probe to analyse the structure of the transforming gene in T24 and other human cell lines, and to monitor transcription of the gene in these cells. These applications require the human sequences in pTB-1 to be contiguous and not rearranged with respect to the chromosomal gene. Such rearrangements frequently occur after DNAmediated transfer into animal cells¹⁷. We therefore compared the restriction endonuclease map of the human sequences in pTB-1 with that of the homologous sequences in T24 DNA. Filter hybridization of T24 DNA cleaved with BamHI and XbaI to the 32P-labelled 1.9-kbp pTB-1 BamHI/XbaI fragment revealed a single homologous DNA fragment (Fig. 5f) comigrating with the 1.9-kbp pTB-1 fragment (lane e), proving that the region extending from the BamHI site to the XbaI site within the transforming gene is not rearranged in pTB-1. The 800-base pair (bp) PstI fragment of pTB-1 (Fig. 5a) mapping between 2.7 and 3.5 kbp from the BamHI site (see Fig. 2) can also be found in PstI-cleaved T24 DNA (Fig. 5b), and this PstI fragment hybridizes to DNA restriction fragments unique to NIH 3T3 secondary transformants of T24 (Fig. 3i–k). These results demonstrate that the 800-bp PstI fragment of pTB-1 is an unaltered component of the transforming gene or its flanking DNA sequences. However, the 2.3-kbp PvuII fragment of pTB-1 (Fig. 5c) spanning 1.7 to 4.0 kbp from the BamHI site is not present in PvuII-cleaved T24 DNA (Fig. 5d), indicating that human DNA sequences more than 3.5 kbp from the BamHI site in pTB-1 are rearranged. Thus, the 1.9-kbp BamHI/XbaI and 0.8-kbp PstI pTB-1 fragments were used as hybridization probes to study the structure and expression of the transforming gene.

Human DNAs are highly polymorphic near the T24 transforming gene

The restriction fragments of T24 and human placental DNAs homologous to the transforming gene were again compared, using the 800-bp PstI fragment of pTB-1 as hybridization probe. The PstI fragment hybridized only to the 8-kbp Bg/II fragment (Fig. 4b) and the 6.8-kbp BamHI fragment (land d) from T24 DNA. The probe detected identically sized Bg/II and BamHI fragments from human placenta DNA (Fig. 4a,c), although the cleaved placenta DNA additionally contains a larger homologous fragment in each case. The presence of these larger fragments indicates the existence of genetic polymorphism near the transforming gene.

To measure the extent of this polymorphism, DNAs from 40 human tumours and tumour cell lines were cleaved with restriction endonuclease BamHI and then analysed by gel electrophoresis and Southern blot hybridization, using the 800-bp PstI fragment of pTB-1 as probe. The data for 21 of these DNAs are shown in Fig. 6. Sequences homologous to the probe were found in DNAs from all human sources, but the number and sizes of the homologous restriction fragments differed among the DNA samples. BamHI-cleaved DNA from each human source contained one, two, or in one case, three discretely sized fragments ranging in molecular weight (MW) from 6 to 9 kbp. Among these DNAs, at least six different homologous BamHI fragments were evident. We have also detected the same extent of restriction endonuclease polymorphism among normal placenta DNAs from different individuals (data not shown).

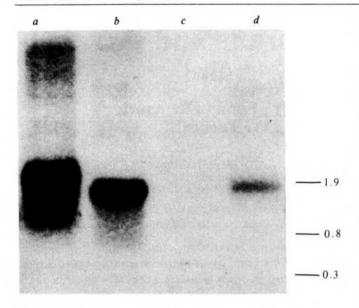

Fig. 7 Hybridization of restriction fragments of pTB-1 DNA to filter-blotted RNA. Total cellular RNAs were prepared by lysis of cells in 4 M guanidine thiocyanate²⁴ and removal of DNA and protein by extraction with hot phenol²⁵. Polyadenylated RNA was selected by oligo(dT)-cellulose chromatography; 5 µg of each poly(A)+ RNA were denatured in formaldehyde/formamide and electrophoresed through a 1.2% agarose gel containing 20 mM MOPS pH 7.0, 5 mM Na acetate, 1 mM EDTA, 2.2 M formaldehyde, and the RNA was transferred to a nitrocellulose filter, with 20× SSC as transfer buffer, as described by Thomas²⁶. The filter was hybridized at 42 °C in 5× SSC, 50% formamide, 10% dextran sulphate with 2 ng ml⁻¹ 800-bp *Pst*I pTB-1 ³²P-DNA fragment and 3 ng ml⁻¹ 1.9-kb *Bam*HI/*Xba*I pTB-1 ³²P-DNA fragment. Poly(A)⁺ RNA from 3T3 secondary transformant T24a2-1 (a), T24 (b), NIH 3T3 (c), HeLa (d). BamHI/XbaI-cleaved and PstI-cleaved pTB-1 DNA provide molecular weight standards (in kilobases).

The hybridization intensities of the homologous BamHI DNA fragments varied among the cleaved DNAs from different tumour sources. This variation is readily explained neither by inaccuracies of DNA concentration measurements nor by incomplete endonuclease digestions among the DNA samples analysed. We therefore suspect that the copy number of DNA sequences homologous to the T24 transforming gene varies about fivefold among the tumours and tumour cell lines.

Expression of pTB-1 sequences in transformed cells

To determine whether the transforming sequences are expressed in T24 cells and in NIH 3T3 cells transformed with T24 DNA, poly(A)⁺ total cellular RNA was prepared from T24 cells, NIH 3T3 cells, a T24 DNA-induced NIH 3T3 transformant and HeLa cells. The RNAs were electrophoresed in formaldehyde/agarose gels, transferred to nitrocellulose filters and hybridized with a 32P-labelled mixture of the 1.9-kbp Bam HI/XbaI fragment and the 0.8-kbp PstI fragment of pTB-1 DNA. The results are given in Fig. 7. NIH 3T3 cells transformed by T24 DNA contain heterogeneously sized RNA species (1,500-1,800 bases) homologous to the pTB-1 fragments (Fig. 7a), while untransformed NIH 3T3 cells show no homology (lane c). A homologous RNA of discrete size (1,100– 1,200 bases) is found in T24 cells (lane b).

The altered size of the transcripts found in NIH 3T3 transformants suggests that certain RNA processing signals in the transforming sequences were lost during gene transfer or are not recognized in the mouse cell host. A homologous RNA of the same size as that in T24 RNA is also found in the HeLa cells (Fig. 7d) but at reduced concentration. HeLa DNA does not transform NIH 3T3 in transfection assays. No homologous RNA species has been found in human placenta (data not shown). These results indicate that the transforming sequences are transcribed, that expression of these sequences is not restricted to T24 cells and that there is differential expression in cells from different sources. We estimate that transcripts of the T24 bladder carcinoma gene comprise 0.01% of poly(A)⁺ RNA from T24 cells.

Discussion

Previous studies using DNA-mediated gene transfer showed that DNA from T24 bladder carcinoma cells can efficiently induce foci of morphologically transformed cells in NIH 3T3 recipients⁶. In this study we have cloned from T24 DNA biologically active sequences which are responsible for transformation. Hybridization studies indicate that the transforming sequences contained in T24 are of human origin and closely homologous sequences are present in DNA from each of 40 different human sources that we have examined.

Of the 21 human DNAs screened, only 5 can efficiently transform NIH 3T3 cells⁶. T24 DNA transfers a different transforming element from the other four active donors; we conclude that the transforming sequences of T24 differ in some critical respect from the homologous sequences found in DNAs from other human sources. The transforming gene of T24 probably did not result from the gross rearrangement of normal sequences, as cleavage of T24 and human placental DNAs with BglII, BamHI, HindIII or EcoRI yields similarly sized fragments that are homologous to the transforming gene. However, the extent of restriction endonuclease polymorphism at this locus in human DNA limits the strength of this conclusion. Further studies should elucidate the origins of the T24 transforming gene and determine whether its biological properties derive from the expression of an altered protein product or from an altered pattern of gene expression.

We thank Dr J. D. Watson for support and encouragement; Drs U. RajBahndary, J. Karns, J. Kwoh and D. Zipser for useful suggestions and for supplying bacterial plasmids, phages and strains; and Dr J. Fogh for supplying human cell lines. M.G. is a Damon Runyon-Walter Winchell Fellow. This work was additionally supported by grants from the NIH and the Robertson Research Fund.

Structure of genes for membrane and secreted murine IgD heavy chains

We have sequenced secreted and membrane terminal exons of the murine immunoglobulin δ chain. The putative transmembranal exon is strikingly similar to that of the μ chain and the internal cytoplasmic exon codes for exactly the same two amino acids, valine and lysine. A third potential exon was found between S and M exons that could code for yet another hydrophilic carboxyl terminus termed δX .

IMMUNOGLOBIN molecules exist in two forms: secreted (s) and membrane (m). Secreted molecules make up the neutralizing antibody population in the circulation and secretory fluids, whereas membrane immunoglobin molecules function as antigen specific receptors on lymphocytes^{1,2}. The majority of mature B lymphocytes strongly express both IgM and IgD on the cell surface with the same idiotype and ligand specificity, and hence, the same variable region³. When the B cell differentiates into a plasma cell upon receipt of an antigen dependent triggering, this same variable region is used for secreted antibody^{4,3}. Although the B cell population expresses surface IgM and IgD about equally⁶, the level of secretory IgD in plasma is about 1,000-fold lower than IgM^{7,8}. This may be due in part to the lower stability of IgD but it also must reflect the fact that cells committed to secretion of IgD must either be quite rare or must secrete δ in small amounts.

The simultaneous expression of two receptors on the B cell surface has led to several theories regarding their differential function. One proposal suggests that membrane IgD may deliver a triggering signal to the B-cell interior whereas membrane IgM provides a tolerizing signal. Another hypothesis holds that membrane IgM conveys a proliferative signal whereas membrane IgD provides a differentiative signal that allows the stimulated B cell to mature to an immunoglobulin secreting plasma cell. Yet another hypothesis holds that an IgD signal be required specifically when T cells are involved in B-cell triggering. Finally it has been proposed that the signal delivered by IgD may be the same as for IgM. in which case the existence of two receptors might serve to improve antigen binding, for example, to antigens with differing epitope density. It is clear that membrane IgM and IgD are not completely interchangeable, for the effect of suppression of IgM bearing cells is a profound immune deficiency whereas suppression for IgD has only minor effects.

Both secreted and membrane immunoglobulins have the same basic structure, but they differ in the amino acid sequence at the carboxyl terminus of the heavy chain. Studies by Rogers et al. 17 and Early et al. 18 on the structure of the messenger RNAs coding for secreted and membrane IgM show that the 3' ends of secreted and membrane mRNAs code for alternative carboxyl terminal amino acids and that these two types of mRNA could result from alternative processing of primary transcripts generated from a single C_H gene. The membrane form of the μ chain has a 41 amino acid hydrophobic carboxyl terminus encoded from two exons located some 1.8 kilobase pairs (kbp) 3' of the $C\mu$ structural gene 18. The secreted form of μ chain bears a shorter hydrophilic carboxyl terminus coded adjacently to the exon coding for the terminal domain, $C\mu 4$.

Both the size and sequence of the two μ mRNAs have been correlated with protein structure data for membrane μ^{19} and secreted μ^{20} .

In the case of IgD, there is also evidence for alternative carboxyl termini and multiple mRNAs. We initially characterized four $C\delta$ exons based on fine structure mapping and nucleotide sequencing of a cDNA clone derived from RNA of the IgD secreting plasmacytoma, TEPC 1017²¹. We also examined $C\delta$ clones of mouse genomic DNA. We found that a distally located exon (DC) encodes a hydrophilic segment which is transcribed as the 3' terminus of the major 1.75 kb δ mRNA of the tumour. Dildrop and Beyreuther²² have shown by amino acid sequence analysis of the mouse δ chain that the carboxyl terminal amino acid sequence of the IgD secreted by the hybridoma B1-8.81 corresponds to the DC encoded sequence (see below). Later we²³ and Moore et al.²⁴ noted the presence of an additional expressed region approximately 1 kbp 3' of the DC exon. We later showed²⁵ that this region hybridized to two larger (2.9 and 2.1 kb) δ chain mRNAs. These species were minor components of the plasmacytoma δ RNA but major components of spleen δ RNA. We proposed that this general region of the genome, termed VDC (or very distally coded), encodes the membrane carboxyl terminus. Maki et al.²⁶ obtained more extensive results and proposed a specific pattern of exons for the 3' end of δ membrane mRNA. Their study was based on the analysis of RNA from hamster-mouse and switch variant hybridomas by examining r-loops between RNA molecules and genomic δ DNA clones. In an IgD secreting hybridoma they found RNA similar in structure to the TEPC 1017 secretory form with the DC terminus. Additionally in both cell types they found membrane form RNA containing sequences from the VDC area with two types of 3' terminal exonic arrangements.

In this article we present a complete DNA sequence analysis of carboxy terminal δ exons correlated with a parallel RNA hybridization study of expression using normal spleen and plasmacytoma RNA as probes. On the basis of these results and those of Maki *et al.*²⁶ and the accompanying results of Fitzmaurice *et al.*²⁷ we present a specific proposal for the structure and RNA splicing patterns of δ mRNA.

Topology of the $\mu\delta$ area

Figure 1a, b presents a scale map of the entire $\mu\delta$ gene complex showing the four exons of the μ constant region, the two exons of the membrane terminus of μ , the three exons of the δ constant region, and the DC and VDC areas located downstream of $C\delta 3$.

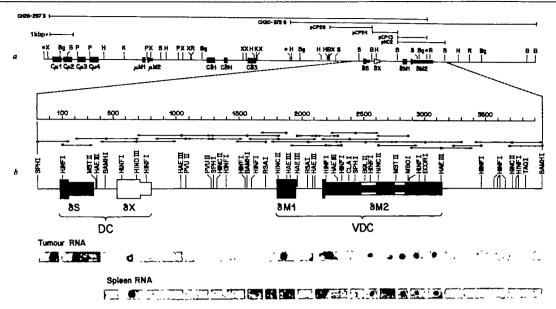

Fig. 1 Map of the $C\mu\delta$ gene complex. a, Restriction map of DNA coding for μ and δ genes is shown. The lines at the top indicate the genomic and pBR322 subclones used for sequence analysis. The exons are indicated by black boxes. Location of all $C\mu$ exons and the structural exons of $C\delta$ ($C\delta$ 1, $C\delta$ H, and $C\delta$ 3) in CH28-257.3 DNA were previously established stress represent end points of clones at Mbol sites. Other sites are abbreviated as follows: X, XbaI; Bg, Bg/II; B, BamHI; P, PsI; H, HindIII; K, KpnI; S, SphI; R, EcoRI. b, Restriction map of sequenced region spanning δ secreted (S) and membrane (M) exons. Boxes denote exons with the raised portion corresponding to sequences that are probably translated into amino acids. The lowered portions of boxes correspond to 3' untranslated regions. The strategy for sequencing by the chemical degradation method²⁹ is denoted by the dots and arrows: Fragments were cleaved and labelled at the dots either on their 5' or 3' ends, and the corresponding horizontal arrows give the direction and length of the sequence obtained; double-ended arrows represent sequences of strand-separated fragments. The scale above is given in base pairs. c, Localization of exons by dot-blot hybridization. Total RNA was isolated from TEPC 1017 or normal spleen, enriched for poly(A)⁺ mRNA by oligo (dT) cellulose chromatography and fractionated for size on sucrose gradients. These mRNA fractions were labelled with ³²P by polynucleotide kinase and hybridized to DC and VDC region DNA fragments immobilized on nitrocellulose according to Thomas³⁰. Autoradiographic results obtained from the critical experimental fragments are displayed beneath the corresponding map positions. The length of the fragments is indicated by vertical lines between the spots.

Two λ phage clones, Charon 28-257.3 and Charon 30-372.6 containing the δ region were isolated from shotgun collections of mouse liver DNA. Subsegments were cloned into plasmids for sequencing by the Maxam-Gilbert method²⁹. The endpoints of the various clones are indicated in Fig. 1a. An expanded map of the sequenced area is presented in Fig. 1b with the sequencing strategy delineated by arrows. The sequence covers approximately 4,100 base pairs (bp), most of which have been sequenced from both strands. Figure 2 shows the complete sequence including the translation into protein of regions that may be expressed, as well as other sites of interest.

Identification of δ exons

The pattern of expression of the sequenced area has been studied by three approaches.

- (1) Radioactive RNA from spleen and IgD secreting plasmacytomas was used as a probe for hybridization to DNA fragments immobilized on filters (Dot-blot method³⁰). These results are presented in Fig. 1c.
- (2) Radioactive fragments from genomic DNA clones were used as probes to detect mRNA species from spleen and tumours by the RNA blot hybridization method³¹. These results are presented by Fitzmaurice et al.²⁷.
- (3) r-loop data presented by Maki et al.²⁶ were scaled up by 10% and superimposed on the sequence with 3' termini aligned with poly(A) addition sites.

As shown in Fig. 1, the sequenced region displays two major zones of hybridization corresponding to the DC and VDC regions. There is no evidence for expression of mature δ mRNA within the approximately 1,000 bp separating these zones, nor 3' to the VDC region, nor 5' between the DC and the C δ 3 domain.

There are two potential exons in the DC area, which are termed δS and δX . The carboxyl terminus of δ secreted by tumours is coded by δS . The region denoted δX seems to be strongly expressed at the RNA level in dot-blot experiments

(Fig. 1c). In the VDC area we find two exons, δ M1 and δ M2, which encode the membrane carboxyl terminus of δ . An intervening sequence occurs in δ M2 in some RNA molecules (Fig. 1c and ref. 26). However, the position of the intervening sequence as measured from r-loops disagrees somewhat with our conclusions based on dot blots. We will discuss each of these exons in turn.

Carboxyl terminal exon of tumour-secreted δ

The carboxyl terminal 21 amino acids of the δ chain produced by myeloma and hybridoma tumours are encoded on the exon located 4.7 kbp downstream of the terminal structural domain, C δ 3. As detailed in the legend to Fig. 2, the genomic DNA sequence differs slightly from the TEPC 1017 cDNA sequence that we published previously²¹ due probably to a reverse transcription artefact. The actual B1-8. δ 1 protein sequence is identical to that which would be coded from the genomic sequence. It is not homologous to the secreted terminus of either μ^{20} or α^{32} .

Within 10-30 nucleotides 5' to the 3' terminal poly(A) tail of all eukaryotic mRNAs, the sequence AAUAAA³³ and, in rare cases AAUUAAA^{34,35}, occurs. An AATAAA poly(A) site which presumably signals the 3' end of δ s mRNA is located 163 bp downstream of the end of the protein. Assuming the actual end of the message is about 20 bp beyond the poly(A) addition site, that 200 A residues are added as a 3' tail and that a typical V region plus leader with 50 nucleotides of 5' untranslated region is present, the calculated length of the full δ s mRNA would be about 1,650 bases. This is in acceptable agreement with estimates of 1,700 to 1,800 bases by gel measurement^{23-27,36}. Likewise, the molecular weight for the secreted, nonglycosylated polypeptide chain calculated from the predicted amino acid sequence coded by the mRNA is 43,800. This is within 1% (ref. 36) and 7% (ref. 26) of reported

Fig. 2 DNA sequence of the $C\delta$ region spanning the secreted and membrane exons. Acceptor RNA splice site junctions are shown as /; donors as \. Positions of introns within the M2 3' untranslated region consistent with the dot hybridization (Fig. 1) (possibility 1) and electron micrographic data²⁶ (possibility 2) are indicated. Poly(A) recognition sequences shown in lower case. The δS sequence given differs from the previously published²⁰ tumour cDNA sequence at positions 296 (deletion), 301 (A), and 360 (T) (see text). Putative amino acids coded by expressed regions are displayed directly above the first base of the corresponding codon in single letter code: Phe, F; Leu, L; Ile, I; Met, M; Val, V; Ser, S; Pro, P; Thr, T; Ala, A; Tyr, Y; terminator, .; His, H; Gln, Q; Asn, N; Lys, K; Asp, D; Glu, E; Cys, C; Trp, W; Arg, R; Gly, G.

size measurements of cell-free translation products of δ chain mRNA.

Possible 'mystery' exon downstream of tumour-secreted terminus

Dot-blot hybridization experiments with both spleen and tumour RNA probes revealed a strongly hybridizing sequence about 300 bp 3' of δ S (Fig. 1). The BamH1-PvuII fragment spanning this region (Fig. 2 nucleotide position 436 to 1,158) also hybridized in RNA blot experiments²⁷ to a minor 2.65 kb RNA present in TEPC 1017. Inspection of the DNA sequence of this region shows that it has signals which might be expected for an expressed carboxyl terminal exon: a consensus acceptor RNA splice site, an open reading frame, a termination codon and a poly(A) addition site. We term this potential exon $C\delta X$. It would encode a 21 amino acid hydrophilic peptide that might serve as an alternative secreted form.

A dominant feature of the δX region is a tandem repeat $(GA)_{16}$ followed shortly by $(GT)_6(AT)_4$ located between the presumed translation terminator and the poly(A) addition site. This repetitive DNA segment in $C\delta X$ may be involved in establishment of secondary structure in δ mRNA. A complementary repeat occurs within the intron separating the $C\delta H$ and $C\delta 3$ domains³⁸ and again in the intervening sequence between the $C\mu M2$ exon and the $C\delta 1$ domain^{28,38} (Fig. 1). These three sequences could interact to form a complex overall folding of the mRNA. Part of this presumed secondary structure was seen previously when clone 257.3 was denatured and examined on electron microscope grids^{23,28}. Such structures may influence the splicing efficiency of δS mRNA in normal B cells.

Transmembranal segment of δ

Examination of the DNA sequence near the beginning of the strongly expressed portion of the VDC region reveals an area of strong homology with the μ gene exon, μ M1, which apparently codes for the transmembrane portion of the IgM

receptor molecule 17,18. Figure 3 shows an alignment of μ and δ gene sequences in that area. In the 120 bp region coding for the most hydrophobic segments of the μ protein, the μ and δ nucleic acid sequences are over 60% homologous. Allowing for a two amino acid gap, 50% of the amino acids match and similar amino acids are substituted at corresponding positions. We conclude that this segment, which we term $\delta M1$, serves to bind IgD to the membrane. The acceptor splice site beginning the δ M1 exon appears to be somewhat upstream of the corresponding site for μ M1, and the amino acid sequence for δ is thus longer by 14 amino acids than for μ . This segment is not particularly hydrophobic and would probably lie on the outside of the membrane. We term this sequence of the protein the 'spacer'. Interestingly, a cystine occurs in this portion of the IgD protein which might serve in cross-linking IgD half monomers (one H and one L chain) to one another on the membrane as was suggested by Eidels³⁹ and Mescher and Pollack⁴⁰.

Cytoplasmic segment of δ

The $\delta M1$ exon has a donor splice site at a position corresponding exactly to the end of the $\mu M1$ exon. Although this could be used to splice to any of a number of acceptor sites further downstream or not used at all, the next exon according to our hybridization results (Fig. 1c), is a region beginning 220 bp further downstream. This area is homologous to the μ M2 exon and splicing to this acceptor would lead to a carboxyl terminal peptide consisting of just two residues, valine and lysine. These are precisely the same amino acids that are found in the membrane form of μ . There is very little direct evidence concerning the amino acid structure of membrane IgD. The present DNA sequence predicts a molecular weight of 47,500 for the unglycosylated polypeptide assuming a typical V_H region and leader segment. This length is within 2% of the estimate of 48,500 for in vitro translation products of δ membrane mRNA²⁶. This agreement would appear to rule out a cytoplasmic component greater than about 30 amino acids. McCune et al. 41 have repor-

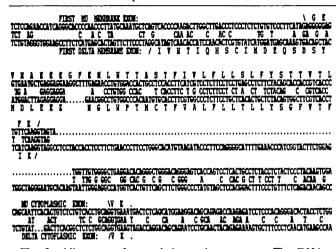

Fig. 3 Alignment of μ and δ membrane exons. The DNA sequence of the μ membrane coding region¹⁸ is shown aligned with the corresponding region of δ . Bases that match are repeated between the two sequences. Proteins coded from these DNA sequences are shown above and below using the single letter amino acid abbreviations. Regions that were gapped to bring the two

sequences into register are shown with dotted lines. RNA splice

sites are shown as slashes.

ted that for the human membrane δ chain no large cytoplasmic domain could be demonstrated by proteolytic digestion of *in vitro* products translated in a microsomal system. This is also consistent with the existence of only a small cytoplasmic protrusion

Beyond $\delta M1$ there are about 15 potential acceptor sites other than $\delta M2$, each of which, if used, would lead to a different carboxyl terminal peptide sequence. Moreover, a donor splice site occurs at the end of the $\delta M2$ exon coinciding with the protein terminator codon so that an array of additional peptides conceivably could be coded beyond the Val-Lys sequence. Since the number of possible mRNAs is quite large, a direct analysis of the membrane δ carboxyl termini at the protein level and analysis of many cloned mRNAs will be needed to establish whether any of the alternative patterns are used. This would be quite difficult if such an event occurs rarely or only during transient states of cellular differentiation.

3' End heterogeneity of δ membrane mRNAs

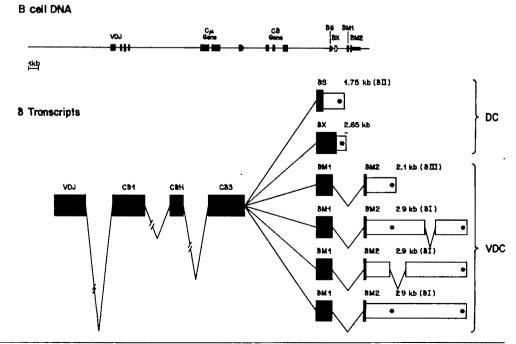

There are two positions at which poly(A) addition sequences occur which could signal the end of the mRNA for membrane

forms of IgD. These are an AATAAA located at nucleotide position 2,680 and an AATTAAA located at position 3,271 (indicated in lower case in Fig. 2). To ascertain whether these are the sites that are in fact used in vivo, two restriction fragments from the region were used as probes to examine mRNA by the RNA blot technique. The first fragment from the ClaI site at 2,568 to the MboI site at 3,035 covered the region between poly(A) addition sites. This DNA hybridized only to the 2.9 kb δ mRNA (ref. 27, Fig. 2). The BamHI (1,748) to ClaI (2,568) fragment derived from the region to the left of both poly(A) sites, hybridized to both the 2.1 kb and the 2.9 mRNA species (ref. 27, Fig. 2). All probes derived from DNA segments located downstream of the HaeIII site (3,303) were negative on both spleen and plasmacytoma RNA preparations. These results thus show that the 3' ends of the two major forms of membrane δ are correlated with the two poly(A) addition sites we have identified by sequence analysis. The simplest interpretation of these data is that the length difference between the two membrane δ mRNAs results primarily from the poly(A) termination site used, and that there is no difference in the protein coded by these two mRNAs. On this assumption the lengths of the two mRNAs can be calculated as 1,920 and 2,510 bases which is in reasonable agreement with the measured sizes of these RNAs. There is precedence for 3' heterogeneity generating multiple mRNAs which code for the same protein in the mouse dihydrofolate reductase gene⁴². The relative abundances of 2.9 and 2.1 kb forms of RNA²⁷ suggest a strong preference for the more 3' of the poly(A) sites. This may be due to the greater efficiency of AATTAAA as a poly(A) site. Secondary structure may also be responsible for this difference.

RNA splicing within the 3' untranslated region of δM

The r-loop data of Maki et al.²⁶ and the dot-blot data of Fig. 1 both indicate the presence of an intervening sequence near the end of the longer (2.9 kb) message. But the two methods suggest different positions for this intron. A model for the possible ways to express this transcription is presented in Fig. 4. On the basis of a computer search for donor and acceptor splice sites, either position for the intervening sequence could be accommodated. In the case of the r-loop data, a donor acceptor pair at 2,944 and 3,018 could be used (possibility 1 in Fig. 2), whereas a pair at 2,644 and 2,806 could be used to accommodate the dot-blot data (possibility 2 in Fig. 2). The latter possibility would be quite intriguing because it would lead to splicing out of the first poly(A) site from the mRNA

Fig. 4 Proposed RNA processing patterns that generate δs and δm RNAs. The upper portion shows a map of the $\mu\delta$ gene complex as arranged in B lymphocyte DNA. The lower portion shows six possible 8 mRNA transcripts with alternative carboxyl terminal exons. Regions of the exons (boxes) in black are translated and regions in white are untranslated. Thin lines denote RNA segments that are spliced out in the mature mRNA and black dots denote poly(A) recognition sites designations of Maki et al.26 for the RNAs are given in parentheses. Note that the same 8 amino acid sequence is obtained from all four δm forms, and that the three 2.9 kb forms differ only in the position (or lack of) the intron in their 3' untranslated region.

which could explain why the second site is used in that message. It is generally thought that polyadenylation precedes RNA splicing⁴³. However, this may not be obligatory in all cases. Thus in δ mRNA the rate of splicing could be rapid relative to that of polyadenylation. Another explanation consistent with our data is that a fraction of the 2.9 kb mRNA is cleaved to the 2.1 kb species and secondarily polyadenylated.

Regulation of δ expression

The μ - δ gene complex is a versatile genetic region which appears to be regulated by almost every known mechanism. Control of mRNA splicing and RNA chain termination are clearly crucial to this regulation, yet almost nothing is known of how this is controlled. Selection of splice sites is precise in the $\mu\delta$ transcript so that exons of μ never are reassorted with those of δ , yet the alternative carboxyl terminal structures of either chain can be simultaneously expressed or shifted in response to cellular signals. Clearly the point of mRNA termination is an important factor in determining where to splice since it can result in elimination of splice sites from the mRNA precursor molecule. We suggest that secondary structure of the RNA, caused by pairing of the repeated sequences we have observed, may also be an important factor in mRNA splicing since these sites could also be eliminated in response to changes in the poly(A) site selected. Thus a considerable degree of control, both quantitatively and qualitatively, could be exerted by alteration of the overall level of transcription termination enzymes in the B cell, ranging from low in the $\mu^+\delta^+$ B cell to high in the IgM secreting cell.

A more subtle regulatory effect is suggested by the phasing of RNA splicing in relation to translation. In both μ and δ the splice from the M1 to M2 exon occurs in exact register with the translation phase. This is in contrast to all other splicings known in immunoglobulin mRNAs where the splice occurs after the first base of the codon register. The use of a different phasing relationship for the cytoplasmic side of the membrane may create a barrier to reassortment of interior with exterior domains, since this splicing would create problems of translation reading frame.

Role of secreted forms of IgD

IgD is different from all other immunoglobins in that both secreted and membrane termini are encoded on separate exons downstream of the body of the C_H gene. Another major difference between IgD and all other Ig's is the lack of a switch-recombination type sequence between μ and δ^{44} that could efficiently create a secretory genomic arrangement by removing the $C\mu$ gene via the Honjo deletion mechanism⁴⁵. This correlates with the apparent lack of IgD plasma cells in young mice and their clonal appearance in old mice⁷. This suggested to us the possibility that IgD may be principally secreted from resting B cells. Considered in this light the IgD molecule may be more analogous to an antigen specific growth factor than to an ordinary antibody molecule. Clearly some efferent signal from the B cell is needed to account for the fact that in B cell-deficient (anti-µ suppressed) animals, antigenand idiotype-specific Lyt-1 bearing helper T cells fail to develop⁴⁶. In this role secretion of IgD could serve as a signal to the rest of the immune network, indicating the B cell population level that is expressing each V region and thus IgD may be central to maintenance of B cell homeostasis. The cessation of IgD production when the B cell differentiates either to an

IgM secreting plasma cell (increased RNA termination) or to an IgG or IgA secreting plasma cell (deleting δ) would both be entirely logical from a structional and functional point of

Do IgD and IgM deliver different signals?

It was to be expected that the general principle of membrane attachment that was demonstrated for μ would apply also to δ , but it is very interesting that the amino acids coded by δ M2 are identical to those of μ M2. This is the portion of the protein that would presumably extend into the cytoplasm and which could deliver a signal to the cell's interior. Our data predict that the signal delivered to the inside of the cell by $\delta M2$ coded IgD would be identical to that delivered by IgM-at least if the nature of the signal is determined by the terminal amino acid sequence exposed to the cytoplasm. However, it is possible that the entire immunoglobulin may be internalized as a result of antigenic stimulation, or other surface proteins (for example, Fc receptors or Ia molecules) may interact specifically with δ and not μ . In this case the two immunoglobins could deliver different signals despite the identical nature of the portions presented to the cellular interior.

Conclusions

With the completion of the DNA sequences of the terminal exons presented here, we have determined the complete structure of the murine $C\delta$ gene. The gene structure leads us to postulate the existence of three forms of the δ protein: δS , δM and δX . The existence of δX , however, remains provisional at present since it is based entirely on nucleic acid data. Our conclusions concerning δ transcription are summarized in Fig. 4. At least six mRNA species coding for δ have been discussed which differ only in their 3' ends. Four of them probably code for the same membrane protein (δM) although additional forms generated by splicing to alternative 3' coding segments cannot be ruled out in lieu of cDNA data.

The gene structure of δ is substantially different from all other immunoglobulins in that the $C\delta$ constant region has only two domains²¹ separated by a long, exposed hinge region. This may lead to the instability of IgD in serum, a feature that would be crucial if the secreted molecule (δS or δX) is to serve as an idiotype bearing chemical messenger as we suggested above.

In membrane δ , a 26 amino acid spacer region separates the last domain from the membrane anchor. This region is completely different for IgD, IgM and presumably for other classes. It thereby is a class-specific marker that can distinguish the immunoglobulin produced by its particular B cell from other irrelevant immunoglobulins that may be cytophilically adsorbed to the surface. In this role the spacer would be a good target for class-specific recognition by T cells or T-cell derived factors that promote maturation and differentiation of the immune response.

As for the antigen-specific receptor functions of IgD compared with those of IgM, the identity of the internal (cytoplasmic) amino acids suggests that the information pertinent to their differential roles does not reside on the inside of the B cell membrane.

IUE observations of variability and differences in the UV spectra of double quasar 0957 + 561 A, B

Since the discovery of the double quasar Q0957+561 A, B by Walsh et al., their proposition that it represents a double image of a single object formed by an intervening galaxy acting as a gravitational lens has been amply confirmed. The intervening galaxy has been detected optically²⁻⁴ at a redshift of 0.36 (ref. 5). Further, a remarkable similarity in fine structure of the radio images has been demonstrated with VLBI observations⁶ and the required frequency invariance of the intensity ratio has been established from the UV through the optical and IR9 to the radio 10 regions of its spectrum. The first UV observations of the double quasar were made with IUE in December 1979, and have been supplemented by data obtained during September and December 1980. Here we present these new data together with an analysis based on the images being a gravitational lens effect.

The log of the new observations is given in Table 1. As previously, the nearby star HD237844 (B3, 9.4 mag) was observed as a comparison. This is necessary because there is some overlap of the two spectra of Q0957+561 A and B; these are separated by a deconvolution procedure which uses the profile of the instrumental point-spread function perpendicular to the direction of dispersion derived from the spectrum of the comparison star. The procedures for data extraction, deblending and correction for instrumental sensitivity are described elsewhere⁷

Because the object is faint (17th mag) for IUE, two separate observations have been made at each epoch and combined to improve the signal-to-noise ratio. For completeness, Fig. 1 covers the previous as well as the present data and shows the mean of two spectra, in 5 pixel bins (~11 Å), of component A (north) and component B (south) in each of the epochs 1979 December, 1980 September and 1980 December. Apart from the continuum, the only spectral features clearly present are the emission and absorption lines of Ly α . Their wavelengths are consistent with the respective redshifts $z_e = 1.41$ and $z_a =$ 1.39 given by Walsh et al.1

From the spectra in Fig. 1, the continuum flux in the range 2,500-2,800 Å and the emission flux in the Ly α (+N V) line were determined (see Table 2). It is evident that no changes have occurred in the spectrum of component B; the intensity of its continuum and $(Ly\alpha + N V)$ emission lines are the same, within the errors, at all three epochs. Component A, on the other hand, shows substantial changes. Its continuum level had fallen by a half by 1980 September and had almost recovered

to its 1979 December value in 1980 December. There is similar but less pronounced variation of the intensity of $(Ly\alpha + Nv)$.

Within the observational limits, the equivalent widths of the emission lines $(Ly\alpha + N V)$ in both components A and B were equal during December 1979 and December 1980 (see Table 2). During September 1980 the equivalent width of emission line in component B was similar (within observational limits) to equivalent widths in components A and B during December but the equivalent width of line in A had increased in the order of 50% compared with line in B, which was greater than the observational uncertainty. It is unlikely that the observed changes in the line and continuum intensity are due to instrumental effects because at the resolution of IUE, vignetting should affect both line and continuum intensities equally. The changes in the equivalent widths of emission lines also indicate that there is a phase lag between a change in the continuum level and the resultant change in the line intensity. Clearly the time grid is too coarse to measure this phase lag but an upper limit of 3 months can be established. This in turn gives an upper limit of 0.1 pc $(H_0 = 50 \text{ kms}^{-1} \text{ Mpc}^{-1})$ for the distance between the source of continuum radiation and the broad line emission region. This separation is an order of magnitude smaller than the separation assumed for modelling the broad line region¹¹.

The fact that the variation has occurred in A is important because any change in the source will be observed in this component first and should then recur in B after the appropriate time delay. To see what information may be available about this critically important parameter, our UV data have been combined with all other currently published intensity data; these are listed in Table 3 and plotted against time in Fig. 2. The range of frequency covered is very large, observations being made in the radio, IR, optical and UV. Where there is overlap there is reasonable agreement between the different observations. Some of the dispersion can be explained by the fact that the optical data include a contribution from the intervening galaxy which varies with wavelength, but the 1980 January observations⁵ at 4,000 Å seem more discrepant than expected from the errors. Over the months April-December 1979, the flux ratio shows no significant change and has the same value, within the errors, in all spectral regions from the radio to the UV. Beyond January 1980, the continuum flux ratio B/A at optical and UV frequencies starts to increase, reaching a maximum during August-September and almost recovers to its intrinsic value by December 1980. Unfortunately only UV observations reported here and available near maximum but the optical data taken immediately before¹² and after¹³ support the existence of the maximum. Table 2 shows clearly that the observed changes are confined to component A, both the continuum flux and $(Ly\alpha + N V)$ emission line flux of component B remaining constant within the error. This could be due to (1) a star in the halo of the lensing galaxy occulting only sight-line A14,15, (2) the lensed quasar being intrinsically variable, a change having propagated along sight-line A but not along B.

If a star in the halo of lensing galaxy occults a sight-line then radiation at all frequencies will be attenuated but line radiation

0957 + 561 A, B	9458	376	8 December 1980

will be attenuated less than continuum radiation as the source of line radiation is more extended than the source of continuum radiation14. At the resolution and signal-to-noise ratio of UV data it is not possible to estimate whether the line radiation has been attenuated more than the continuum radiation. On the other hand, if the lensed quasar is intrinsically variable then UV radiation is more likely to keep in step with visible radiation than with radio emission. The trend in the visible data is very similar to the trend in the UV data. Lacking the crucial radio data for September 1980, we conclude from the present observations that the lensed quasar is intrinsically variable but that during 1979 April-December the entire lens system was stable and no changes were propagating through this system and the observed mean ratio $B/A = 0.74 \pm 0.01$ represents the intrinsic ratio for the lensing system. Around August-September 1980 a change occurred in the lensed quasar and this change has been propagated along sight-line A but had not arrived along sight-line B by 1980 December and this allows us to place a lower limit on the delay time $\Delta T(B-A)$. At the 3σ level, changes have occurred in both the continuum and $(Ly\alpha + N V)$ emission fluxes of component A in 1980 early May and are still undetected in B in 1980 December. Hence,

 $\Delta T(B-A) > 0.6 \text{ yr}$

Current theoretical estimates of the time delay are very uncertain because it depends not only on the mass distribution in the lensing galaxy but also the mass distribution, both visible and hidden, throughout the cluster of which it is the brightest

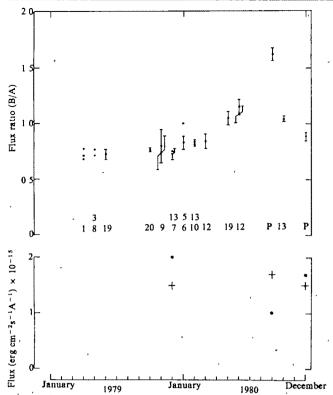

Fig. 2 The variation in the flux ratio QSO(B)/QSO(A) during 1979-80 (upper plot) and the measured UV continuum fluxes (2,500-2,800 Å) from QSO, A(●) and QSO, B(+). The numbers are references from which data were obtained; P, the present data.

member. Hence, from a grid of assumed positions for the cluster centre, Dyer and Roeder¹⁶ obtained time delays in the range 0.03-1.7 yr. With extensive new CCD observations of the surrounding cluster of galaxies and a more detailed modelling, Young et al.5 are able to fit the data with time delays of up to ~5 yr. Clearly, the observational limit given above restricts the range of possible models and continued monitoring to detect the same event in component B should give an actual measurement of the time delay. Because this scales inversely as the Hubble constant H_0 there is, in principle, the exciting possibility of measuring this out to z = 1.4, but uncertainties in the mass distribution of the lensing galaxy and surrounding cluster are too great to make an unambiguous determination of H_0 from a single time delay between two images. Young et al.5 point out that a good estimate of H_0 might be possible if two time delays, one between image A and B and a second between A. or B and as yet unobserved third image, were measured.

The equivalent widths of the Ly α absorption lines occurring at a redshift z=1.39, were also measured in the IUE spectra and are listed in Table 2 with the rest-frame values in brackets. As with the other measurements given in Table 2, these are made from the mean of two spectra taken of each component at three different epochs. These are reproduced in Fig. 3 but, unlike Fig. 1, they are unbinned and only cover the region of the Ly α line. An accurate estimate of the standard error is not possible in this case as a major uncertainty arises from drawing in a continuum in the neighbourhood of the emission component; we judge that the mean value for each component has an accuracy in the range 10-20%. The resulting column densities given in Table 2, derived on the basis of radiation damping, are therefore accurate to $\sim 20-50\%$.

Clearly the Ly α absorption in component A is greater by a factor of 2 than in B. The separation of the two light paths in the region of absorption is therefore a measure of the spatial structure in the absorption system. If we assume that the absorption system is at a cosmological distance then for $H_0 = 50 \,\mathrm{km \, s^{-1} \, Mpc^{-1}}$, a separation of $\sim 0.5 \,\mathrm{kpc}$ is obtained for the two absorption regions. The column density $\sim 10^{20} \,\mathrm{cm^{-2}}$ for H I

in this region is higher than the values obtained for the halo of our Galaxy $(\sim 10^{19} \text{ cm}^{-2})^{17}$. If, however, the absorption system is intrinsic to the QSO and represents remnants of ejecta from the quasar then an upper limit to its distance from the QSO can be established by assuming that it has been moving at its relative velocity of $\sim 1,900 \text{ km s}^{-1}$ for $\sim 10^6 \text{ yr}$, the longest kind of lifetime expected for quasars¹⁸. This gives an upper limit on distance of ~2 kpc, which in turn gives an upper limit to the separations of the two absorption regions of $\sim 10^{17}$ cm.

We thank the staff of the IUE Observatory (VILSPA) in Spain for assistance and hospitality.

Following the submission of this paper, two reports^{21,22} of ground-based photographic photometry of the double quasar have appeared. Within the errors the intensity ratios B/A given in these papers agree with our results, that is they show a gradual increase up to June 1980 and a decrease from October 1980. (The maximum departure as revealed by IUE occurred during the intervening period when the double quasar was inaccessible to ground-based optical observations.) However, the two sets of optical data^{21,22} indicate that component A remained constant and that B varied, whereas our results indicate the exact opposite.

We believe that only further observations will resolve this contradiction. For any reasonable lens model for the double quasar³, events occurring in component A will be followed by similar events in B. Thus the optical observations indicate that variations in A must have occurred in the past, while our results indicate a forthcoming variation in B. The various lower limits on the delay time deduced from the respective data will obviously depend on which data are confirmed. We can predict that the UV and optical intensity of B will fade by a factor of ~2 over a period of months. This is best tested by continuing to monitor the object in the optical and UV; if positive, it will give an unambiguous measurement of the delay time.

Asteroid rotation rates depend on diameter and type

Stanley F. Dermott & Carl D. Murray

Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853, USA

The rotational frequency of main-belt asteroids is shown here to depend on both asteroidal type and diameter. If asteroids of any one diameter are considered, then, on average, M asteroids rotate faster than S asteroids which in turn rotate faster than C asteroids. This shows that asteroids which have been classified by their surface properties alone have different bulk properties. For all three types, although the dispersions of the frequencies are large, we prove that the mean frequency increases linearly with the mean diameter. In both the C and S plots of mean rotational frequency against mean diameter there are discontinuities at diameters \sim 125 km and \sim 105 km, respectively, which may differentiate primordial asteroids from their collisional products.

Rotational frequencies of asteroids have been controversial ever since Alfvén¹ pointed out that all bodies except the Sun in the Solar System that have not been affected by tidal braking display an approximate isochronism of spin. Publication of opinions on the dependence of rotational frequency on asteroid diameter and type has since kept pace with the growing data.

McAdoo and Burns², for example, using a sample of 64 asteroids, claimed that smaller asteroids rotate more rapidly than larger ones. More recently, using a sample of 182 asteroids, Harris and Burns³ also concluded that there is a tendency for the smaller asteroids to rotate faster than the larger ones. However, they also concluded that there is little change in rotation rate with size when either C- or S-type asteroids alone were considered and that C-type asteroids appear to rotate ~80% less rapidly than the other asteroids. They consider that this, together with observational selection effects, could account for the apparent size dependence of the frequency distribution of the sample as a whole. (Various surface properties are used to separate asteroids into a small number of distinct groups. The chief difference between C and S asteroids is their albedos: C asteroids are much darker than S asteroids. For a complete discussion of the CSM asteroid classification scheme see ref. 9.)

Tedesco and Zappalà used data on 321 asteroids to define a set of 134 main-belt asteroids having reliable, photoelectrically determined rotational periods. Their criteria for inclusion in the set were designed to minimize observational selection effects and to isolate a set of asteroids with similar histories. With this set they were still unable to find any definite relationship between asteroid size and rotation rate but, in contrast to Harris and Burns, they recognized a group of large asteroids (diameter ≥175 km) that appear to rotate faster than the rest of the sample. They also found, like Harris and Burns, that S-type asteroids tend to rotate faster than C-type asteroids but concluded that the difference was statistically insignificant.

Burns and Tedesco⁵ concluded that there is no statistically significant size dependence for rotational frequency within either the S or C taxonomic type, but asteroids with diameters >175 km do rotate faster than the rest. They also consisder that a much larger data base is needed if any trends that do exist are to be discerned. We now show that this is not the

case. By analysing the same data set as that used by Tedesco and Zappalà⁴ we show that trends do exist in the data.

The data are shown in Fig. 1a: any trend is not apparent to the eye, but there is a significant linear correlation between rotational frequency and diameter. By ordering the chosen population in diameter and calculating running means, we can plot the mean rotational frequency against the mean diameter (Fig. 2a). In Fig. 2a the running box always contains 19 (= n) asteroids and was shifted through the chosen population one asteroid at a time.

The central limit theorem (see, for example, ref. 6) allows us to relate σ , the standard deviation of the distribution of the means of the samples, to σ_p , the standard deviation of the chosen population by

$$\sigma = \frac{\sigma_{\rm p}}{\sqrt{n}} f(N, n) \tag{1}$$

where n is the number of objects in each sample taken from a population of N objects, and

$$f(N, n) = \left(\frac{N - n}{N - 1}\right)^{1/2} \tag{2}$$

is a correction factor which allows for the fact that sampling

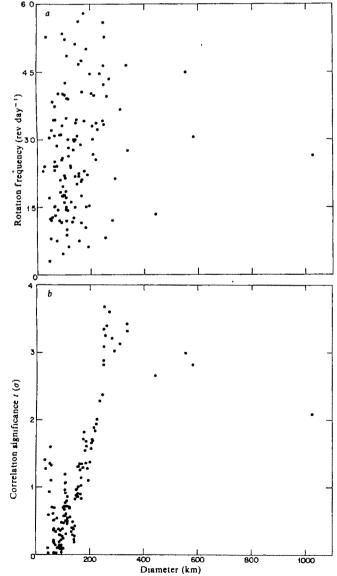

Fig. 1 a, Rotational frequency and diameters of 134 main-belt asteroids with reliable photoelectrically determined rotational periods. All data are from ref. 4. b, Variation of the statistical significance (σ) of the linear correlation coefficient with increasing diameter for the data shown in a. Note that the correlation is greatest for the 130 asteroids with diameters <400 km.

takes place without replacement: the first asteroid in the sample is chosen from N asteroids, whereas the nth is chosen from N-n+1.

Figure 2a shows clearly that rotational frequency increases with asteroid diameter. The mean rotational frequency increases linearly from a minimum of 2.1 rev day^{-1} (period = 11.1 h) for asteroids of diameter 60 km to a maximum of 3.7 rev day^{-1} (period = 6.5 h) for asteroids of diameter 230 km, that is, the mean frequency increases linearly from a point $2.0 \text{ } \sigma$ below the mean to one $3.5 \text{ } \sigma$ above.

The running box method gives a good description of the dependence of rotational frequency on diameter, but with this method it must be remembered that because each box contains 19 (=n) asteroids from a population of 134 (=N), then there are only $7 (\sim N/n)$ independent groups of data. Plots of the mean frequencies and the mean diameters of such independent groups for various values of n (19, 11 and 7) are shown in Fig. 2b, c, d. The uncertainties in the mean frequencies of these groups were estimated from the sample variances and in each case they compare well with the expected uncertainties estimated from the variance of the population as a whole.

We do not find any evidence of a discontinuity at diameter 175 km. Any trend that exists in the data seems to be present throughout the whole population. There is a suggestion, however, that mean rotational frequency does not increase indefinitely with mean diameter, but reaches a plateau of ~3.5 rev day⁻¹ (period ~7 h) at diameter ~230 km. However, because the population contains asteroids of different taxonomic types these values are not suitable for direct interpretation.

A useful measure of the significance of the correlation between rotational frequency and diameter is given by the linear correlation coefficient r. The statistical significance of r can be estimated from

$$t = r \left(\frac{N-2}{1-r^2}\right)^{1/2} \tag{3}$$

and if N is large ($\geqslant 100$) then the distribution of t can be assumed to be normal and t then represents the number of standard deviations (σ) from the mean. Figure 1b shows the correlation significance t as a function of increasing diameter D'. That is, the asteroids were ordered in diameter and t and t were calculated for those asteroids with diameter t of t with that t increases steadily with increasing t to some value t of the maximum is t of the maximum is t of the largest four asteroids in our chosen population causes t to decrease. In fact, if all asteroids including Ceres are included then t is reduced to t of the largest four causes t to decrease. In fact, if all asteroids including Ceres are included then t is reduced to t of the largest four causes t to decrease. The file containing rotational periods in the Tucson Revised Index of Asteroid Data (TRIAD) is maintained by Tedesco⁸. Quality codes are used to indicate the reliability of the quoted data. Quality 1 indicates that the quoted period has been estimated from observations covering less than a complete rotation cycle. Quality ≥ 2 indicates secure results, that is, the rotational period is known to within a fraction of 1 h or better.

The 134 asteroids defined by Tedesco and Zappala are all of quality ≥ 1 , and include 48 S-, 45 C- and 9 M-type asteroids. Data describing the frequency (ω) and diameter (D) distributions, that is, the mean rotational frequency (ω) , the mean diameter (D) and the standard deviations σ_p of each subset of M-, S- and C-type asteroids are given in Table 1. Table 1 also contains data for those asteroids in the set of 134 with rotational periods of quality ≥ 2 . Running box plots of the data in Fig. 3a show that the tendency for mean rotational frequency to increase with diameter, which we have proved to exist in the data set as a whole, is not determined by the data in any one subset but is equally present in all three subsets of M-, S- and C-type asteroids: the tendency is a characteristic common to all major asteroidal types. Running box plots for the better quality data (quality ≥ 2) are shown in Fig. 3b.

Subsets: 1, photoelectrically observed, main-belt asteroids with rotational periods of quality ≥1 listed by Tedesco and Zappala⁴; 2, as 1 but only asteroids with rotational periods of quality ≥2. These subsets are further divided by taxonomic type.

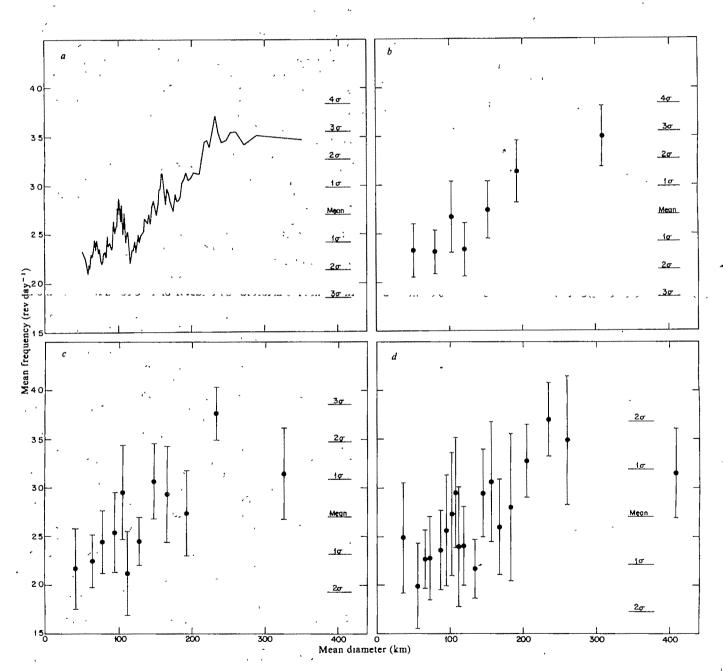

Fig. 2 a, A plot of the mean rotational frequency against the mean diameter for the 134 asteroids shown in Fig. 1 obtained by applying a running box method to the chosen population which were sorted in order of increasing diameter. The σ levels are derived by the application of the central limit theorem to the distribution of the mean of the samples of the population. The running box (and hence each sample) contained 19 asteroids and was stepped through the population one asteroid at a time. Mean rotational frequency clearly increases with mean diameter reaching a plateau ~3.5 rev day (period ~7 h) at mean diameter ~240 km. In b, c and d we show plots where the ordered data are shown in independent groups of b, 19; c, 11; d, 7 asteroids. The uncertainties in the mean frequencies were estimated from the sample variances and in each case they compare well with the expected uncertainties (shown at the sides) estimated from the variance of the population as a whole.

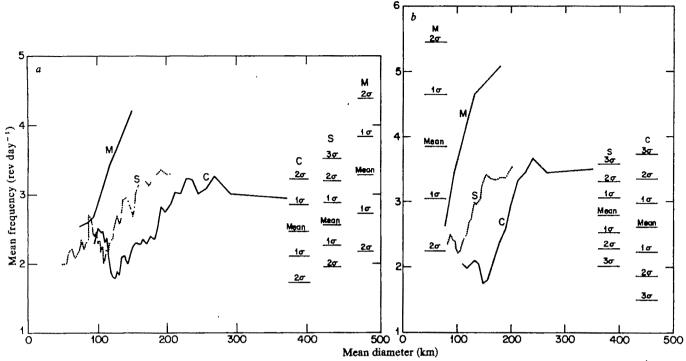

Fig. 3 A plot of the mean rotational frequency against the mean diameter for M, S and C asteroids listed by Tedesco and Zappalá and shown in Fig. 1, obtained by applying a running box method to the data which were sorted in order of increasing diameter. In a all data of quality ≥ 1 were included whereas in b only data of quality ≥ 2 were used. For the S and C plots the running box contained 10 asteroids. For the M asteroids the running box contained five asteroids in a and three asteroids in b. In all cases the box was stepped through the data one asteroid at a time.

The curves for each subset, but particularly those for S- and C-type asteroids, which are, of course, the best determined, are strikingly similar and contain several interesting features. Not all of these features are of strong statistical significance, but the fact that they are common to both the S and the C curves persuades us that they are probably real.

Each curve contains a near-linear portion for which we can write

$$\omega = mD + \omega_0 \tag{4}$$

Values of the slope m and of the intercept ω_0 for each nearlinear portion are given in Table 1. All the values of m, but particularly those derived from the better quality data, are very similar. In both the S and the C curves shown in Fig. 3b there is a suggestion of a plateau at mean frequency $\sim 3.\overline{4}$ rev day⁻¹ (period ~7 h). There are also significant discontinuities at small diameters. These are particularly evident in Fig. 3a which contains more data on asteroids with small diameters. The discontinuity on the C curve in Fig. 3a occurs at mean diameter of \sim 125 km at which point there is a 2σ increase in mean rotational frequency. A similar increase occurs on the S curve at mean diameter ~105 km. We consider that the observed increases in mean rotational frequency could be due to fragmentation of asteroids on collision and that the discontinuities may divide primordial asteroids from their collisional products.

The most important feature of Fig. 3, however, is that the curves for M-, S- and C-type asteroids are separate. If asteroids of any one diameter are considered, then, on average, M asteroids rotate faster than S asteroids which in turn rotate faster than C asteroids. As we have proved that rotational frequency does depend on diameter and because the M-, Sand C-type asteroids in our chosen population have different mean diameters, it follows that a simple comparison of the mean frequencies of the different subsets is of little value. We need a method which shows the dependence of rotational frequency on both diameter and type and the plots shown in Fig. 3 are ideal for this purpose.

We consider, but we cannot prove, that the discontinuities at small diameters and the plateaus shown in Fig. 3 are probably real. If this is the case, then the linear portions of the plots probably have the greatest significance. Using Fig. 3b and the data describing the linear portions of the plots given in Table 1, we can see that at any one mean diameter S asteroids rotate faster than C asteroids by a factor of 1.48 rev day⁻¹. For the S and C asteroids this represents a difference in mean frequency of ~2.6\sigma. Tedesco and Zappala5 found the same dependence on type for S and C asteroids but not the large statistical significance. However, they averaged their data over a very wide range of diameters and only compared the mean rotational frequencies of one group of asteroids from each subset. Our method allows us to examine the dependence of mean rotational frequency on mean diameter and on asteroid type in a single diagram and in such a systematic way that we can see that for all mean diameters S asteroids rotate faster than C asteroids. In fact, the separation of the curves is such that it makes better sense to state that if any one mean rotational frequency is considered, then, on average, C asteroids are significantly larger than S asteroids which in turn are significantly larger than M asteroids. (Note that the latter statement is not based on Figs 2 and 3, but on plots, not shown here, of mean rotational frequency against mean diameter derived from data ordered in rotational frequency rather than diameter.)

The running box method of averaging data has two advantages over a conventional histogram. (1) All points on a given curve are based on data for the same number of asteroids and therefore all points have equal weight. (2) The trend and structure in a given data set and some indication of their statistical significances can be displayed in a single diagram.

Resonant absorption by water polymers in the atmosphere

H. A. Gebbie

Department of Electrical Engineering, Imperial College of Science and Technology, Exhibition Road, London SW7 2BT, UK

There is much evidence both from atmospheric¹⁻⁹ and laboratory^{10,11} measurements that water vapour can show absorption of millimetre waves in addition to that predicted by models based on monomers¹² and dimers¹³. Constituents other than water can be eliminated as the cause of the extra absorption which is characterized by having a structured spectrum, increasing more rapidly with decreasing temperature than is expected from equilibrium phenomena and in the atmosphere showing a highly variable strength which is not simply correlated with total water content. The steep temperature dependence suggests invoking non-equilibrium water species to provide an explanation and this will account for variability as well as giving new prospects for understanding the spectral structure. A nonequilibrium model has, however, to be reconciled with what is known about supersaturation. It also opens the question of the nature of the energy source which is maintaining the steady state and allowing the extra absorption to be observed. I suggest here that water polymers containing about 50 molecules can, by collective acoustic resonances and postulated transition dipole moments, explain the observed component of absorption of millimetre waves by the atmosphere in some conditions. The polymers are metastable and are almost certainly the cause of supersaturation in cloud chambers but in these their lifetime is much greater than in the atmosphere.

Some examples of the structured spectra observed in high saturation and stable conditions given by natural fogs are shown in Fig. 1b, but the variability of the phenomenon causes most atmospheric observations to have poorer reproducibility than is shown by these. This has led some authors 14,15 to question the existence of anomalous absorption and to suggest that experimental artefacts could explain the effects. The data in Fig. 2 counter this by showing that measurements made by different experimental techniques used at different sites have an underlying common behaviour. They also show that this cannot be attributed to simple variations in the amount of water in the path. Low or zero values of anomalous absorption in some atmospheric conditions are to be expected and indeed were invoked to account for a few of the observations reported in ref. 5. The non-equilibrium nature of anomalous absorption also makes it difficult to interpret directly temperature dependence measurements specifically aimed at examining the role of equilibrium water dimers. There is, however, provocative evidence in finding high values of ~1 eV in the exponent of a Boltzmann factor describing results where the dimer binding energy would give ~0.2 eV. The high values are also supported by cloud chamber observations shown in Fig. 3 in which nonequilibrium conditions were deliberately created. The interpretation of these temperature exponent values will be discussed later.

To explain the spectral structure, the polymers are modelled as spherical liquid droplets which are assumed to show macroscopic surface tension behaviour. (Droplet is defined here as a liquid drop of such a size that an appreciable fraction of its molecules are on the surface. It may or may not contain a minority concentration of foreign atoms and may or may not be charged.) They will then have predictable collective acoustic modes with eigenfrequencies determined by droplet radius but if these are to be effective in electromagnetic absorption the major assumption must be made that the oscillations are accompanied by transition electric dipole moments. No values for

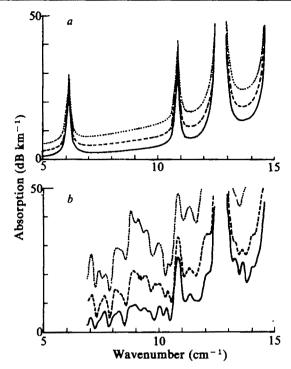

Fig. 1 a, Predicted spectra for fogs comprising molecular absorption and particle loss computed from standard models: corresponding to visibilities of 50 (···), 100 (---) and 150 (----) m. b, Spectra observed in the atmosphere corresponding to the models. The standard deviation in the measured spectra is 3 dB km⁻¹. In such fogs the liquid drops are all small compared with the wavelengths and show Rayleigh region behaviour in which attenuation varies monotonically. Neither this component nor equilibrium dimers can account for the observed additional structure between the monomer lines.

these are known but arguments for their existence can be given from considering the molecular structure of droplets of appropriate size. A molecular model for the polymers is also necessary to account for the complexity of the observed spectra. Classical macroscopic arguments applied to measurements of supersaturation are, however, sufficient to show that droplets in the required size range exist in cloud chambers and there seems to be no reason that droplets with the same size distribution should not be found in the atmosphere with a much reduced lifetime. This could be as small as 10^{-10} s and droplets could still be effective in millimetre wave absorption. Their existence in the atmosphere is supported by the measured temperature dependence of absorption giving high values of exponents.

dependence of absorption giving high values of exponents. The formulation of the theory uses results due to Kelvin-Gibbs (equation (1)), Frenkel¹⁶ (equation (2)) and Landau-Lifshitz¹⁷ (equation (3)) relating the quantities S = supersaturation ratio; $v_m = \text{molecular volume in liquid phase}$ (cm³); $\sigma_R = \text{radius corrected surface tension (erg cm²²)}$; R = droplet radius (cm); $R_c = \text{droplet radius at critical supersaturation (cm)}$; $G = \text{the droplet free energy at critical supersaturation radius } R_c$ (eV); $\rho = \text{liquid density (g cm³³)}$; $\omega = \text{acoustic capillary wave angular frequency in a sphere of radius } R$ (Hz); l takes integral values 1, 2... n with l = 2 the lowest value for the droplet to depart from sphericity; $\omega = 2\pi c\bar{\nu}$ where $\bar{\nu}$ is in cm¹ for electromagnetic waves as justified; c = speed of light (cm s³¹). The three relationships are plotted in Fig. 4.

$$\log_{e} S = 2\sigma_{\rm R} v_{\rm m} / R_{\rm c} kT \tag{1}$$

$$G = \sigma_{\rm R} R_{\rm o}^2 4\pi/3 \tag{2}$$

$$\omega = \sigma_{\rm R} l(l-1)(l+2)/\rho R^3 \tag{3}$$

The values of surface tension have been corrected for dependence on R by the expression proposed by Tolman¹⁸ and though controversial its inclusion does not affect the arguments in any

0028-0836/82/130422---03\$01 00

critical way. The capillary waves are surface modes which for droplets will become the dominant acoustic eigenfrequencies. Further, as they describe motion of the liquid interface with free space and if accompanied by changes in dipole moment, the angular acoustic frequency can be related to electromagnetic oscillations using the free-space value for the speed of light.

If the curves of Fig. 4 are to be the basis of the kind of spectral structure shown in Fig. 1b, evidence must be given that some special significance can be attached to specific values of R. This comes in part from PVT observations¹⁹ in cloud chambers showing that if ions are not excluded a critical supersaturation ratio of about 4 cannot be exceeded but that at the critical value a long-lived state can be produced. Fig. 4a,b show that the corresponding specific droplet radius and free energy are $\sim 7 \times 10^{-8}$ cm and ~ 0.8 eV respectively.

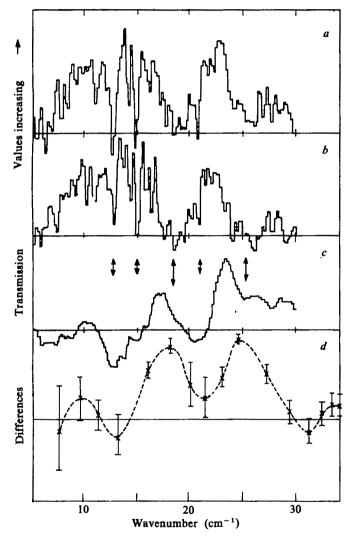

Fig. 2 a, b, Individual spectra of atmospheric emission measured successively within 30 min at Mount Evans, Colorado (see ref. 4). They represent relatively stable daylight conditions and show consistency in predicted water monomer and oxygen features but considerable variation at other wavenumbers. The difference between the two spectra shown by the smoothed curve of c has wavenumber maxima which do not coincide with the water lines indicated by the arrows and has both positive and negative values. It cannot therefore be attributed to varying amounts of water monomer. Curve d (derived from ref. 22) comes from a solar transmission spectrum observed at Gornergrat, Switzerland, with differences from prediction obtained by calibration with a black body. Again d has both signs and the resemblance to c which suggests that the cause of the differences is an atmospheric phenomenon common to the two sites and observable by different experimental methods.

·

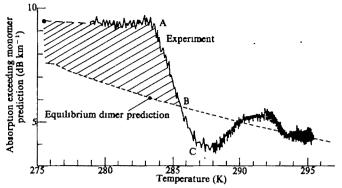

Fig. 3 Results on the temperature dependence of absorption of radiation in a band extending from 7 to 30 cm⁻¹ by a mixture of water vapour and argon. The gas had been expanded adiabatically to a supersaturation ratio of 2.5 in a cloud chamber and the solid line represents the observed changes in absorption on its relaxing to room temperature. This behaviour differs considerably from a model shown by the dotted line which is based on equilibrium dimers being the only addition to water monomers. The actual absorption is attributed to metastable droplets for which, using the assumptions in the text, a free energy of ~1.8 eV can be deduced by comparing the observed slope with the predicted slope at point B. This is based on dimer binding energy being 0.18 eV per molecule. The result is taken from unpublished work by W. B. Johnson et al. of Rutherford-Appleton Laboratory.

The latter represents an energy maximum which acts as a barrier to nucleation and maintains the unstable equilibrium. While there is a local minimum in droplet density at the critical radius there is also a local maximum in droplet lifetime which is an operationally important quantity in supersaturation though classical theory does not consider this. While it cannot be rigorously proven there is also reason to believe that the coincidence of long lifetime with the energy maximum is responsible for the measured temperature dependence of millimetre wave absorption giving characteristic energies of the order of 1 eV and thereby pointing to the existence of droplets in the atmosphere of about the same size. Although these energies came from equilibrium analyses it seems that the Arrhenius type plots^{11,20} used were indicative of reaction rates rather than energy levels but that these quantities are likely to be related.

While these arguments can provide a basis for a specific radius value and hence with Fig. 4c single peaks in the spectrum for each I value, the behaviour shown in Fig. 1b suggests that a more complex distribution of droplet free energy with size must be found. Classical macroscopic theory cannot provide this so results are given from a model which considers the effects of molecular behaviour within the droplets. The model is due to Plummer and Hale²¹ and their values of energy for droplets with discrete values of n between 40 and 57 are shown by crosses in Fig. 4b. These show large variations in droplet energy with radius or a kind of 'magic number' behaviour where Frenkel's relation is monotonic. Because droplet densities will vary exponentially with energy and it seems reasonable to assume that the variation in absorption cross-section with nwill be much slower, the Plummer and Hale values can be translated into changes in absorption with wavenumber which can be compared with observation. The calculated absorption change in going from n = 55 to n = 57 which corresponds to a spectral interval $\Delta \bar{\nu}$ of ~0.5 cm⁻¹ is ~60 dB km⁻¹. The maximum change of observed absorption in the same wavenumber interval in the region of 8 cm⁻¹ is ~15 dB km⁻¹. This shows that inclusion of molecular binding conditions can to a first order account for the observed spectral structure if the existence of transition dipole moments associated with the capillary wave oscillations can be justified. Also, from considering the molecular structure of droplets with $n \sim 50$ these moments are seen to be plausible. Macroscopic arguments require that both the total energy of the droplet and its surface energy be minimized and any molecular model must respect these conditions.

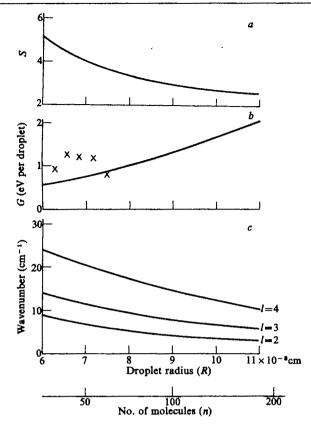

Fig. 4 Three quantities plotted against droplet radius R and the corresponding number of water molecules n. a, The supersaturation ratio S when the radius has the critical value R_{c} given by equation (1) (Kelvin-Gibbs). b, The droplet free energy, G for the critical radius, Re given by equation (2) (Frenkel) with the crosses representing droplet energy for specific n values of 40, 45, 50, 55 and 57 given by the model of Plummer and Hale²¹. c, With the assumptions of the text gives the eigenwavenumbers $\bar{\nu}$ for electromagnetic absorption by droplets of radius R according to equation (3) (Landau-Lifshitz).

It seems unlikely that an additional constraint can then be imposed on a given size of droplet containing only about 50 polar water molecules with marked steric properties that it should show no change in dipole moment when constrained to make the changes in shape with l value required by equation (3). The condition for complete absence of structured absorption is even more stringent in that the transition dipole moments would have to be zero for all values of n in the range of interest for all capillary modes. These incidentally have a degeneracy value of (2l+1).

The existence of metastable species raises the question of what are the likely sources of energy which are maintaining steady-state conditions. While no definite answer can be given as to whether the energy source is acoustic or electromagnetic in origin note that many of the observations in which the most marked anomalous spectral structure was observed were made in bright sunshine and that refs 22 and 23 are of particular interest in this connection. On the other hand in the laboratory measurements reported in ref. 11 no high energy photons were involved but the untuned resonator contained a source of acoustic power. In a purely acoustic experiment²⁰ high values of temperature exponent also suggest droplet formation.

The implications of the presence in the atmosphere of metastable absorbers and the need for energy sources to excite them greatly complicates the prediction of millimetre wave attenuation values. This complexity will almost certainly extend to other spectral regions²⁴ and will need to be considered in explaining observations. However, resonant absorption measurements could become a valuable new probe for the study of supersaturation.

An important feature of the present proposal is the introduction of collective acoustic oscillations and results on rough metal surfaces in the 4-12 cm⁻¹ range from Raman scattering have been explained in the same way²⁵. A generalized treatment of the onset of collective modes has been given by Fröhlich²⁶ and this may contain the means of removing, at a later stage, the ambivalence of the present proposal which comes from the simultaneous use of classical and molecular model results. A great benefit of using the Landau-Lifshitz capillary wave formulation is that eigenfrequencies are given in terms of macroscopic parameters and thereby a useful starting point is obtained. I know of no other experimental results using the formulation but its use has been proposed to predict the behaviour of globular proteins²⁷ in scattering inelastic neutrons and the scattering of light by superfluid helium²⁸.

I am supported by the Science and Engineering Research Council. Much of the work reported here was done at the Appleton Laboratory and I thank colleagues there for the use of results before publication.

Multi-armed vortices in an active chemical medium

K. I. Agladze & V. I. Krinsky

Institute of Biophysics, USSR Academy of Sciences, 142292 Pushchino, Moscow Region, USSR

An excellent example of self-organization in nonequilibrium systems^{1,2} is the origination of rotating spiral vortices. These vortices have been observed in a wide range of active media-in the morphogenesis processes of social amoeba Dictyostelium discoideum^{3,4}, in cardiac muscle during some arrhythmias⁵ and in the Belousov-Zhabotinsky reaction⁸⁻⁹. All these vortices are simple spirals. The rotating structures of a higher order of symmetry such as multiarmed vortices have not previously been observed experimentally. We have obtained two-, three- and four-armed rotating spiral vortices in an active chemical medium. These structures were appreciably stable and we observed their rotation for more than half an hour, which was in striking contrast to unstable multiple vortices in many other physical systems (such as superfluid ⁴He or superconductors^{10,11}).

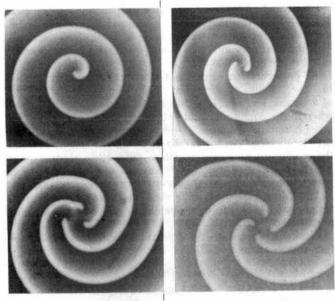

Fig. 1 One-, two-, three- and four-armed vortices in an active excitable chemical medium. A Petri dish 90 mm in diameter was filled with 4.5 ml of reagent similar to that proposed by Winfree: 0.3 M NaBrO₃; 0.4 1 M H₂SO₄; 0.1 M CH₂ (COOH)₂ 0.85 M CHBr(COOH)₂; 0.045 M ferroin.

The multiarmed vortices were obtained as follows. Two, three or four waves were initiated close to each other by touching the solution with a silver pin. Wave-breaks were then induced by stirring a little of the reagent with the pin. One drop of 1 M KCl was placed close to the wave-breaks, and the waves began to circulate around it as though it were an obstacle (Cl⁻ interferes with the oxidation-reduction chemistry¹²). After one or two rotations the drop was removed by a strip of filter paper, whereupon a multiarmed vortex arose. The number of its arms equalled the number of waves preceding its appearance. The

idea of this procedure was to begin with a regime which would be *a priori* stable, and then change to the regime we were studying.

To increase the accuracy of measurements and to avoid the influence of the small amount of Cl⁻ that remained in the reaction mixture, the vortex was displaced outside the domain occupied previously by the drop of KCl solution. This was achieved by passing through the solution a train of concentrational waves with a frequency exceeding that of the vortex. Thus, the vortex could be shifted without displacement of the liquid 13.

The vortices obtained are shown in Fig. 1. Far away from the core, the multiarmed vortices form equidistant rigidly rotating spirals in accordance with the well known solution (2) of the reaction—diffusion equation. But in the core region the wave behaviour has proved to be unexpectedly complex: there was no simple rotation; instead, waves were intermittently connected as shown in Fig. 2. The geometry and the kinematics of the waves in the vortex core would not fit the modern theoretical concept of vortex rotation (see equation (2)).

The periods of waves (T) sent into the medium by multiarmed vortices were found to increase with the number of arms: $T_1 = 28 \pm 1$ s, $T_2 = 29 \pm 1$ s, $T_3 = 31 \pm 1$ s, $T_4 = 34 \pm 2$ s (the mean from 7-15 experiments \pm s.d.).

All multiarmed rotating structures exist as long as the chemical reaction runs (>30 min). However, we also observed the decay of vortices. Figure 3 shows the disintegration of a two-armed vortex into two one-armed vortices. The disintegration was usually observed 50-60 min after mixing the reagents. Apparently, the disintegration was due to the change in active medium parameters with time. The two-armed vortices almost always decayed after 60 min of reaction life.

The decay of a three-armed vortex was observed in only one of seven experiments. However, in none of the experiments was the decay of a four-armed vortex evident. At the same time, all types of vortices were perfectly stable to external perturbations. The increase in temperature by 15 °C gave rise to a 2-2.5-fold decrease in the wavelength and the period, but

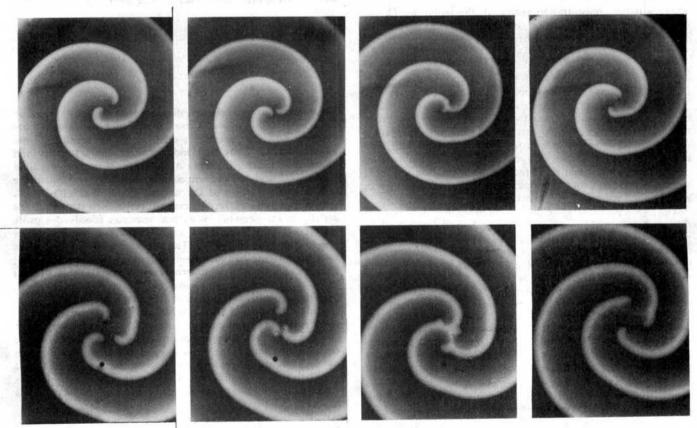

Fig. 2 Wave movement in the core of two- and three-armed vortices. Time interval is 15 s. Other conditions as in Fig. 1.

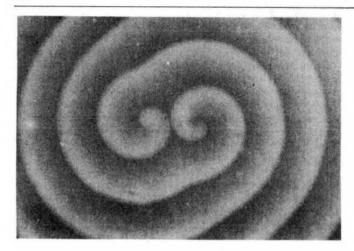

Fig. 3 Two closely spaced one-armed vortices formed from a two-armed vortex. The photograph was taken 58 min after mixing the reagents.

no signs of disintegration of multiarmed vortices were seen. In experiments where a multiarmed vortex was shifted by highfrequency concentrational waves, the structure of both the core and the outer region of the vortex was drastically changed, but in each experiment the vortex regenerated on switching off the external source of high-frequency waves.

Although similar structures to the multiarmed rotating vortices can be seen on some photographs of the aggregation of D. discoideum, these are not rotating waves. They are motionless and represent the path along which the cells are moving, whereas the form of the rotating concentration wave of cyclic AMP is a single one-armed spiral.

Active media are governed by the parabolic partial differential equation (the so-called reaction-diffusion equation):

$$\frac{\partial \mathbf{u}}{\partial t} = D\Delta \mathbf{u} + f(\mathbf{u}) \tag{1}$$

where \mathbf{u} is the concentration vector; Δ , the laplacian; D, the diagonal matrix of diffusion coefficients. The vortex-like solutions of this equation of the form

$$\mathbf{u} = F(N\theta - \omega t, r) \tag{2}$$

are known¹⁰ where r and θ are the polar coordinates, and N is the integer number or the topological charge of a vortex 10,11.

This solution describes the rigid rotation of a vortex with a constant angular velocity ω in a two-dimensional medium. Note that in a three-dimensional medium the centres of rotation form a thread—the axis of a vortex—which may be straight or curved 9,10 . The topological charge N characterizes the number of arms in a vortex and the direction of its rotation $(N = \pm 1,$ a one-armed vortex rotating clockwise or anti-clockwise; N = 2, a two-armed vortex; N = 0, concentric waves).

The topological charge of the system of vortices is conserved during their formation, disintegretion and annihilation both in physical systems and in active media-vortices emerge only in pairs with topological charges of opposite sign-a vortex with topological charge 2 may disintegrate into two simple vortices with topological charges 1, and so on.

Vortices with a topological charge N > 1 have been analysed with regard to the theory of superconductors, superfluid ⁴He and modern field theories ^{11,14}. As the vortex energy is directly proportional to N^2 , vortices with a topological charge N > 1are unstable in the physical systems considered. Similar results have been obtained by the theory of active media consisting of the van der Pol oscillators. It has been shown that unidirectional vortices repulse each other, which results in instability of vortices with N > 1 (ref. 10). These findings were the basis of the widespread opinion that the multiarmed rotating vortices cannot exist in real active systems because they must decay into simple ones as fast as formed.

How could we observe longlasting vortices with a topological charge N > 1? Note that energy is not conserved in active media. the waves propagate at the expense of local energy sources. Therefore, energy analysis, though successful in many other cases, is not applicable here. Linear analysis of the stability to small perturbations carried out after our experiments shows that the stability of vortices strongly depends on the kinetics of an active medium. In particular, for two-component media wherein the equilibrium state of each element is unstable, the quasi-harmonic solutions corresponding to vortices with a sufficiently large topological charge N are also unstable. But if the equilibrium state becomes stable, the vortices become stable for all values of N (ref. 15). Note that we obtained vortices with topological charges 2, 3 and 4 in a strongly relaxational excitable (not oscillating) active medium. However, no theoretical approach seems to be available to analyse vortex stability in that case.

We thank Professor A. M. Zhabotinsky and Dr A. M. Pertsov for valuable advice.

Surface microlayer phenolic enrichments indicate sea surface slicks

David J. Carlson*

Department of Oceanography, University of Maine at Orono, Walpole, Maine 04573, USA

The realization by early investigators that oil films spread on surfaces of bodies of water could mimic slick conditions 1-3 has evolved into the present model of slicks resulting from monomolecular films that modify wave characteristics and hence reflectance properties of surfaces. However, the lipid materials postulated to form monomolecular layers constitute only a small fraction of the organic material in either bulk seawater or at the surface 4-7, may not retain their strong surface activity in the presence of natural seawater dissolved organic material (DOM)8, and have not been found in any consistent relationship with slicks^{7,9-11}. The apparent association of slicks with macroalgae has also been noted¹²⁻¹⁵, but there has not been a demonstration of macroalgae-derived DOM in slicks. I show here that enrichments of UV-absorbing phenolic materials, consistent components of surface microlayers16, offer reliable indication of slick conditions. I then suggest that: (1) slicks result not from monomolecular films, but from viscosity changes in surface microlayers caused by more soluble organic components; and (2) the occurrence of slicks therefore depends not on absolute concentrations of surface-active materials, but on relative viscosity differences. Evidence is also given demonstrating the presence of macroalgae-derived phenolic materials in slicks.

Present address: Environmental Chemistry Branch, Code 4330, Naval Research Laboratory,

Surface microlavers were collected from Maine estuarine and coastal waters and from the North Atlantic ocean by the glass plate method^{17,18}. Microlayer samples and appropriate reference bulkwater samples were each filtered through precombusted, rinsed glass fibre filters. The filtrates were assayed for phenolic materials using UV absorbance at 280 nm in 10 cm quartz cells and a modification of the Folin-Ciocalteu test and for DOC by persulphate oxidation and IR detection^{20,21}. Microlayer enrichments were calculated as the ratio between the concentration of a substance in microlayer and in bulkwater samples. Particular attention was given to surface conditions at the time of sampling. The following classification system was used: (1) certified slicks—visually obvious slicks with at least some distinct boundaries; (2) slick influenced samples—conditions in which, although distinct boundaries were absent, the surface had some combination of stable bubbles, particulate debris, or viscous appearance during sampling which was characteristic of certified slicks; (3) mixed samples—samples in which some dips of the plate were in areas designated as certified slick or slick influenced surfaces and some were in clean areas;

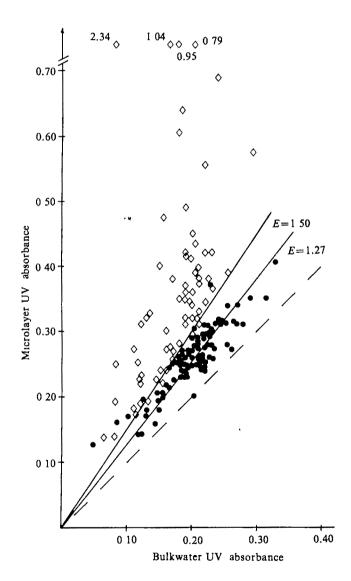

Fig. 1 Microlayer phenolic content versus bulkwater phenolic content, as measured by absorbance at 280 nm. Data were collected May 1978 to August 1981 from estuarine, Gulf of Maine, and North Atlantic (39° N, 66° W) waters. Lowest line indicates equal absorbance in microlayer and bulkwater samples. Line with slope of 1.27 $(r^2 = 0.99)$ denotes mean phenolic enrichment of clean microlayer samples. Line showing enrichment of 1.50 represents boundary between clean and slicked microlayers. •, Clean surfaces; \diamondsuit , slicked surfaces.

Clean

and (4) clean surfaces—no slicks, no visible accumulations of debris, stable bubbles rare or absent.

The slick data are summarized in Table 1, with clean surface data included for comparison. Only the phenolic materials showed a consistent relationship to slick conditions. All three slick classifications had mean phenolic enrichments greater than did clean surfaces. The mean phenolic enrichment in certified slick samples was significantly greater (P < 0.05) than the mean enrichment in slick influenced samples, with the mixed sample enrichments intermediate to and not significantly different from either the certified or influenced samples. In contrast to the phenolic materials, slick DOC enrichments were not significantly different (P > 0.05) from clean enrichments. Although the highest DOC concentration was in a dense slick, high DOC concentrations were not consistently related to the occurrence of slicks. DOC data from Pacific coastal and oceanic waters were similarly non-representative of the presence of slicks14. DOC as measured undoubtedly includes, in addition to relatively insoluble materials contributing to surface enrichments, varying quantities of more soluble materials. Therefore, it is not surprising that neither enrichments nor concentrations of DOC were reliable indicators of slick conditions. Phenolic materials are, however, preferentially enriched in microlayers relative to DOC¹⁶, and they represent the first fraction of DOC which consistently indicate slick conditions.

The slicks were distinguished by enrichment of phenolic materials rather than by concentration (Fig. 1). Slicks were evident throughout the UV absorbance ranges of both subsurface and microlayer samples, indicating that no minimum amount of phenolic materials was necessary for slicks to appear. Instead, the line representing an enrichment ratio of 1.50 clearly distinguished slicked from clean surfaces. This observation, that slicks were indicated by relative (enrichment) rather than absolute (concentration) measures, independent of the type of material measured, is inconsistent with the model of wavedamping by an incompressible film. In that model, wavedamping requires some critical concentration of surface-active molecules, independent of bulkwater concentration, above which slicks should ideally always be evident and below which no slicks should occur. The phenolic evidence indicates a relative relationship-slicks becoming evident when the UV absorbance in the microlayer reaches a ratio of 1.50 relative to the UV absorbance in bulkwater, compared with an average clean surface ratio of 1.27. I propose that the relative nature of the slicks observed here, indicated by phenolic materials, is due to relative differences in microlayer viscosity.

In organic-free seawater, damping of capillary waves at a clean interface is related to the viscosity of the seawater²². Organic materials in natural seawater will alter the viscosity of both the bulk seawater and, if they accumulate near the surface,

^{*} Range is range of enrichments; ranges of absolute values, in units of absorbance at 280 nm and mg 1^{-1} DOC, respectively, are in parentheses.

[†] Data set excludes extreme values from a dense slick so as not to bias comparisons with other categories. Extreme value is included in next data set. ‡ Data included from ref. 14.

of the surface microlayer where the viscosity changes may be enhanced by interfacial effects. When the amount of organic material in a microlayer increases the viscosity relative to bulk seawater and to adjacent but less enriched microlayers so that wave characteristics are altered, slicks will become evident. Slicks thus become a function of the viscosity in surface microlayers rather than of the compressibility of a monomolecular film, and the appearance of slicks depends on relative viscosity differences between slicked and clean microlayers, both relative

One implication of a relative viscosity hypothesis is that at a constant bulkwater viscosity, a microlayer viscosity gradient should exist between fully clean and fully slicked surfaces. In confirmation of this, the slick influenced samples did have a mean phenolic enrichment intermediate to clean and certified slick samples. In addition, in situ measurements of 'film pressures', which are generally performed without definitive demonstration of the presence of surfactant monolayers, probably represent an interaction not between the spreading oils

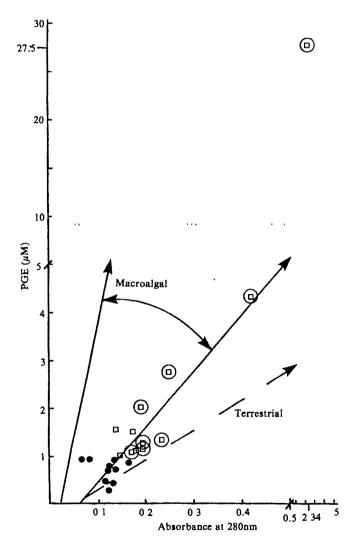

Fig. 2 Absorbance at 280 nm plotted versus phenolic reactivity expressed as micromoles of phloroglucinol equivalent (PGE). Dashed line indicates ratios typical of terrestrially-derived phenolic materials, while solid lines outline ratios of macroalgal-derived materials . Sources of bulkwater (), clean microlayer (□) and slicked microlayer (□) materials with absorbances <0.20</p> cannot generally be distinguished. However, in some slicks with higher absorbances and reactivities, ratios indicated macroalgaederived material. Samples collected October 1979, August 1980, and August 1981 in coastal waters of the Gulf of Maine, 0-30 km offshore. Salinity ranges: 29.5-33%. Scales change at 0.5 absorbance and at 5 µM PGE.

and a monolecular film but between the spreading oils and the natural microlayer organic materials. From this viewpoint, there is some evidence of a gradient from clean surfaces to weak and then sharply defined slicks²³ which supports the suggestion of the relative nature of slicks.

A second implication is that as the concentration of DOM in both clean and slicked microlayers increases in response to increased bulkwater DOM, the viscosity will also increase. Although the appearance of a slick in one area will depend on viscosity differences relative to clean surfaces in that area, both the slick and clean surfaces should have greater viscosities and different capillary wave characteristics relative to slick and clean surfaces in an area of lower bulkwater DOM. For example, in the low DOM North Atlantic samples, visual distinction between slicks and clean surfaces was less certain than in coastal waters, perhaps because of lower surface DOM concentrations and lower viscosities. It is possible that such differences between areas of different DOM, for both clean and slicked surfaces, might be detectable and quantifiable by remote sensing instruments, and alternatively, might affect measurements by such instruments.

It remains then to consider the UV-absorbing phenolic materials as constituents of slicks, and their sources. The IR evidence of Baier²⁴ suggesting highly hydroxylated components in natural slicks could apply to phenolic materials. A polymeric nature has been suggested for terrestrial and macroalgal materials showing phenolic characteristics^{25,26} and the phenolic materials might be expected to interact with amino acids, car-bohydrates, or lipid materials²⁷⁻³⁰ to form complexes similar to hypothesized microlayer compounds 7,24,30. The complex chemistry of the phenolic materials in seawater precludes assigning DOC values to their UV absorbance (refs 31, 32 and D.J.C., L. M. Mayer and M. L. Brann, unpublished data). There are, however, indications that microlayer materials and substances extracted from fucoid macroalgae can increase the solution viscosity of seawater³³, although it remains difficult to extrapolate that information to viscosities in microlayers.

It has been shown that in low UV absorbance, low phenolic content offshore and oceanic waters, it is difficult in both bulkwater and in microlayers to distinguish terrestrial and macroalgal sources for the phenolic materials¹⁶. In slicks, however, where the amounts of UV-absorbing materials can be large, there was definite evidence that macroalgae-derived phenolic materials contributed to slick DOM (Fig. 2). In Maine coastal waters, macroalgae have a seasonal exudation pattern³² which, perhaps accompanied by seasonal changes in reactivity of the exuded phenolics (D.J.C., L. M. Mayer and M. L. Brann, unpublished data), may contribute to the seasonal occurrence patterns of slicks11

The above observations do not preclude other compounds, such as lipids, as components of slicks, or negate physical slick formation processes, such as convergences. However, whatever the formation processes and regardless of additional components, enrichments of UV-absorbing phenolic materials provided consistent indications of slick conditions in all coastal waters sampled. It is possible that phenolic materials may be ubiquitous components of clean and slicked surface microlayers and might serve as indicators of slicks in other areas, especially coastal areas, of the oceans.

I thank the faculty, staff, and students of the Department of Oceanography, University of Maine, for assistance and encouragement. Supported by NSF: OCE-79-20244.

Peat materials are economically and ecologically valuable and so their dating is important. The lead isotope 210Pb $(22.26\pm0.22 \text{ yr})$ has had great value in dating recent deposits1-8 of the past 150 yr. But the varying conditions in different water reservoirs, and the possibility that the mathematical models used in ²¹⁰Pb-dating will give different results, call for additional chronological data. ¹⁴C-dating has major difficulties in this respect⁸⁻¹⁰ and dating with ¹³⁷Cs and ²³⁹Pu is not reliable ¹⁰⁻¹³. Previously ²¹⁰Pb-dating has been tried on only seven peat cores from ombrotrophic mosses: four from Denmark^{14,15} and three from England and Ireland¹⁰. We present here a comparison of ²¹⁰Pb results with moss-increment dates of selected peat material from Finland.

Two Sphagnum fuscum hummock cores from two Finnish peatlands, Kärpänsuo bog, Kuhmoinen (61°35' N, 25°20' E), core 1, and Kunonniemensuo bog, Kitte (62°05' N, 30°10' E), core F9, were used in this study. These cores had been previously dated by the moss-increment method^{11,16}. Both sampling sites are small, ombrotrophic, raised bogs with scattered small pines (Pinus silvestris L.) and derive their water supply exclusively from precipitation. The average water table in both hummocks is ~30-35 cm below the peat surface. The average peat depth at the sites is ~4 m. Most of the peat moss layers had grown in ombrotrophic conditions (according to pollen analysis these layers are younger than 6,000 yr BP), while the bottom layers of 50 cm or so were formed in minerotrophic conditions. The hummocks from which the cores were taken are several metres in diameter. They consist of a very loose S. fuscum carpet with dwarf shrubs such as Empetrum nigrum. Some Polytrichum strictum was found at both sites and the annual increments of this species served as a dating tool. The cores were taken with the 12-cm diameter steel corer and cut into sections, 2.5-5.0 cm thick. The peat material was slightly decomposed white moss (Sphagnum)11,16

The shape and microstructure of the individual mosses were used to identify the annual increments. These could be distinguished in Sphagnum by means of cyclic pigmentation¹⁷ branching pattern and changes in growth direction caused by pressure from the snow cover 11. About 15-20 stems of Sphagnum mosses and/or P. strictum vertically penetrating the peat sections were measured to determine their actual lengths after straightening. From these stems, the annual increments (which include 1 yr of growth) were identified 19 and their lengths measured. In the case of very short increments a stereomicroscope (×150) was also used to observe the changes in the stem pigmentation. The average number of years within each section was calculated by dividing the mean stem length with the mean increment length, so the values used represent an age interval in moss-increment years. Because the averages of the age intervals were not statistically weighted, no statistical distribution of the moss-increment years in the age intervals were given 11,16

Materials in the same peat samples were analysed for their ²¹⁰Pb contents at the Institute of Physics, Uppsala, Sweden and the Technical Research Centre of Finland, Espoo, Finland. The samples from the Kärpänsuo bog, core 1, contained only peat moss (S. fuscum) materials and all the visible high (vascular) plant remains were excluded. The samples from Kunonniemensuo bog, core F9, comprised the entire peat material. However, the percentages of the vascular plants were low in

all but the deeper subsamples.

The 'total' ²¹⁰Pb was measured in the two laboratories by determining the granddaughter product ²¹⁰Po by means of the isotope dilution. The ²⁰⁸Po was used as an internal yield tracer in both laboratories. These tracers were calibrated against different standards. The chemical separation of polonium samples in the two laboratories is described elsewhere 6,20,2 The samples were counted by α spectrometry using silicon surface barrier detectors. The long-term stability of these detectors was considered22. The radon emanation was used in Uppsala to determine ²²⁶Ra (ref. 23). The ²²⁶Ra was separated from the sediment residues, with the help of Ba-carrier, and kept in closed bottles for a month. A nitrogen gas was then used to flush the ²²²Rn to an ionization chamber that was carefully examined for impurity and adsorption effects^{6,20} in

The total ²¹⁰Pb of the peat samples comprises ²¹⁰Pb of atmospheric origin; unsupported ²¹⁰Pb and an additional *in situ* part which is produced from ²²⁶Ra; and supported ²¹⁰Pb. The supported ²¹⁰Pb may not always be in secular equilibrium with its precursor ²²⁶Ra. Supported ²¹⁰Pb was estimated at Espoo only from the total ²¹⁰Pb of samples older than 200 moss-increment years. The unsupported ²¹⁰Pb for such samples should be <2%. In Uppsala the ²²⁶Ra $(t_{1/2} = 1,620 \text{ yr})$ was also used to evaluate the supported ²¹⁰Pb. The ²²⁶Ra values of five samples, three of them being taken from one core, are in good agreement and the average value is 0.12 ± 0.04 pCi g⁻¹. This value agreed with the total ²¹⁰Pb values in the deeper samples showing 200-500 moss-increment years; the averages of the two laboratories are 0.07 ± 0.01 pCi g⁻¹ and 0.19 ± 0.03 pCi g⁻¹ for core F9 and core 1 respectively.

²¹⁰Po $(t_{1/2} = 138 \text{ days})$ is assumed to be in equilibrium with ²¹⁰Pb $(t_{1/2} = 22.26 \pm 0.22 \text{ yr})$ in all but the surface slice (²¹⁰Po reaches secular equilibrium with ²¹⁰Pb in about 2 yr). This assumption is valid only in ideal cases of closed systems in which neither the ²¹⁰Pb nor the ²¹⁰Po is subject to any kind of translocation in the time interval of interest. This assumption was confirmed in a sediment core²⁴. Lewis²⁵ estimated a mean residence time for metals similar to ²¹⁰Pb in organic-rich soils to be about 2,000 yr. Mosses of ages younger than 700 yr showed that 95–99% of the total lead is either bound or sorbed to the peat materials. Jacobsen 15 found that selected suboceanic ombrotrophic peats from Denmark have a very high capacity for retaining metals and could be used to give good records on atmospheric deposition, especially for lead 'petrol lead'. Pakarinen and Tolonen²⁶ claimed that mobility of lead might

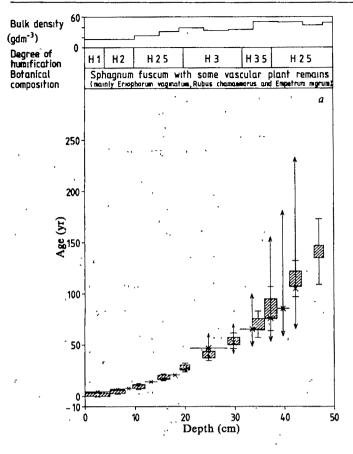

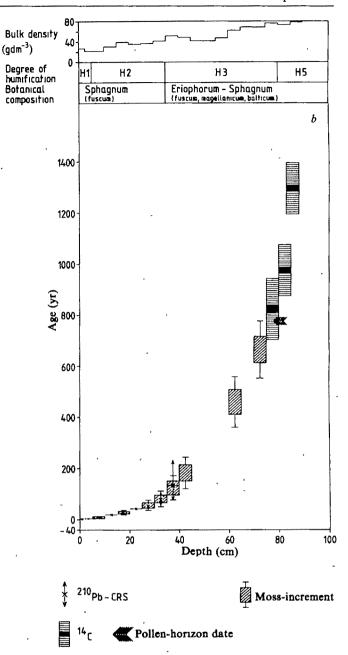

Fig. 1 Ages-depth profiles of peat layers from two Finnish Sphagnum-hummocks: a, Kärpansuo bog, core 1; b, Kunonniemensuo bog, core F9. Ages, in moss-increment years, are before 1975. Vertical bars represent, $\pm 1\sigma$, of the ²¹⁰Pb ages (Uppsala results) or average error for the moss-increment years. The lengths of the rectangles represent either the moss-increment age intervals or the uncertainties in the ¹⁴C ages.

affect the chronological order of the atmospheric lead in peat and give rise to enriched horizons.

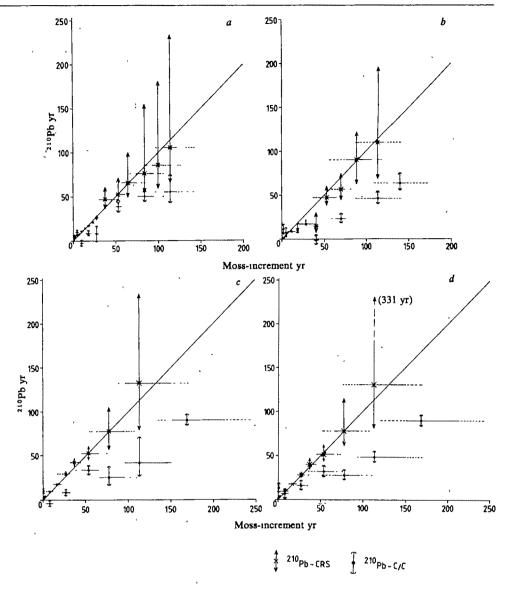

The ages of the peat layers from the Kärpänsuo bog, core 1, and the Kunonniemensuo bog, core F9, are given in Fig. 1: in moss-increment years these are before 1975 and their errors were based on direct observations. The ²¹⁰Pb-concentrations (per unit dry weight) which were measured at Uppsala and Espoo, using different chemical extractions and independently calibrated tracers, allow tracing of systematic errors in the laboratories and lend credibility to the evaluation of the ²¹⁰Pb models. The uncertainties in the ²¹⁰Pb values included not only the statistical uncertainties in the 210Po activity measurements but also those due to the 208Po tracers, the corrections of the polonium peaks for the silicon-detector instabilities (performed only in Uppsala) and the supported ²¹⁰Pb activity. For ²²⁶Ra, the uncertainties included the counting statistics, the background of the ionization chamber and the efficiency of the filling system as determined by a standard sample. The ages in ²¹⁰Pb yr were calculated using the constant initial concentration (CIC) and the constant rate of supply (CRS) models^{27,28}. The ²¹⁰Pb concentrations of the past 20–30 moss-increment years (the upper 15-20 cm) were normalized for their radioactive decay and a σ -weighted average was calculated for each core and laboratory. These averages served as initial concentrations for the studied cores (CIC model), and smoothed down horizontal variations of bulk densities and growth rates which took place in the surface peat layers. Such variations may cause the 210Pb concentrations to differ from place to place even if the atmospheric supply rate of the 210Pb was constant. These values, as calculated with aid of the least

squares method, were: for core 1, Kärpänsuo bog $5.50\pm0.22~\mathrm{pCi}~\mathrm{g}^{-1}$ for Uppsala and $4.70\pm0.35~\mathrm{pCi}~\mathrm{g}^{-1}$ for Espoo; for core F9, Kunonniemensuo bog, the Uppsala value was $5.43\pm0.27~\mathrm{pCi}~\mathrm{g}^{-1}$ and for Espoo $5.99\pm0.44~\mathrm{pCi}~\mathrm{g}^{-1}$. For the CRS model the integrated activities over the past 150 yr were: for the Kärpänsuo core, $33.3\pm3.0~\mathrm{nCi}~\mathrm{m}^{-2}$ and $44.8\pm3.6~\mathrm{nCi}~\mathrm{m}^{-2}$ for Uppsala and Espoo respectively; the corresponding values were $49.2\pm3.3~\mathrm{nCi}~\mathrm{m}^{-2}$ and $47.3\pm2.9~\mathrm{nCi}~\mathrm{m}^{-2}$ for the Kunonniemensuo core.

Figure 1 shows the age-depth relation for both cores. The 210 Pb ages, as calculated using the CRS model, show good agreement with the moss-increment dates. The radiocarbon dates for some deeper layers from core F9, Kunonniemensuo bog, are also given: Helsinki-1140, 75–80 cm, 800 ± 120 yr BP; Helsinki-1053, 80-85 cm, 950 ± 100 yr BP; and Helsinki-1141, 83-88 cm, $1,270\pm100$ yr BP. The dates were derived using Libby's half life (5,570 yr). The samples were used without further physical pretreatment and without the NaOH-insoluble fraction being dated. Unfortunately no δ^{13} C values are available to correct for the isotopic fractionation but if the suggested values for peat materials which range from -19% to -35% are used, an age correction by 95 to -145 yr could be expected.

Fig. 2 A comparison between the ²¹⁰Pb years as calculated using the CIC and CRS models and the moss-increment years of the Kärpansuo bog, core 1: a, Uppsala results; b, Espoo results and the Kunonniemensuo bog, core F9; c, Uppsala results; d, Espoo results. Vertical bars represent standard deviation, $\pm 1\sigma$, of the ²¹⁰Pb ages; the horizontal bars give the age intervals of the peat layers with their average errors in broken bars.

Thus, the 14C dates show good agreement with the mossincrement dating and the distinct onset of rye cultivation at 80 cm, which according to pollen studies by Vuorinen on an adjacent varved lake (Hinnisenlampi), occurred ~AD 1200. The bulk density of the top moss layers is lower than the underlying layers because of either or both compaction and decomposition of the peat materials. For both cores the CIC model underestimates age compared with the moss-increment method (Fig. 2) which suggest higher initial concentrations of the 'unsupported' ²¹⁰Pb in the deeper moss layers. This coincides with the calculations made on the annually accumulated dry matter which showed lesser net accumulation for the earlier peat layers 11,16. The CRS model shows a good agreement with the moss-increment method (Fig. 2). All the dates agreed within $\pm 1\sigma$ except for three dates from Espoo (the Kärpänsuo core) which deviated by -2σ . Note that the CRS model gives rise to higher statistical uncertainties in the final ages. As one moss-increment year represents a growing period which corresponds quantitatively to one calendar year, it seems likely that the atmospheric rate of the ²¹⁰Pb supply during the past 150 yr was constant, the annual peat layers of the cores effectively accumulated the available ²¹⁰Pb during their growth and the peat material behaved as a 'closed' system.

Seasonality and mean annual sea surface temperatures from isotopic and sclerochronological records

Douglas F. Williams*, Michael A. Arthur*, Douglas S. Jones† & Nancy Healy-Williams*

* Department of Geology and Belle W. Baruch Institute, University of South Carolina, Columbia, South Carolina 29208, USA † Department of Geology, University of Florida, Gainesville, Florida 32611, USA

Seasonality is one of the most dramatic climatic variables affecting the physical and biological properties of the surface of oceans. Attempts to deduce the seasonal temperature contrast of past oceans using the fossil record have led investigators to explore the carbonate growth patterns in certain marine invertebrate organisms. In many cases these growth patterns represent annual growth increments analogous to annual rings in trees1. Just as tree rings contain a record of terrestrial climates2, systematic variations in the physical or chemical properties of annual growth increments in the skeletons of marine organisms record the environmental or climatic properties of the marine realm. Several investigations have called attention to the use of stable isotope profiles in growth increments of mollusc shells to determine the seasonal water temperature changes³⁻ seasonal timing of coastal upwelling8. Mollusc shells therefore have the potential of revealing much information about past environmental changes9, particularly along temperate continental shelves where our knowledge of the palaeoceanographic history is very limited. We have now used coordinated isotopic and sclerochronological (growth increment) studies to compare the geochemical history of shell growth in Spisula solidissima with the physical oceanographic history of the Middle Atlantic Bight and determine whether the isotopic records of S. solidissima from different water depths on the continental shelf reflected the seasonally different thermal regimes at those depths. We chose S. solidissima because it is widely distributed along temperate continental shelves, its shell growth and life history are well understood^{9,10}, and the genus has a fairly wide distribution in Plio-Pleistocene fossil deposits. Jones 11,12 has already established through a detailed sclerochronological analysis of S. solidissima that a 10-20 yr time series of mean sea surface temperature trends can be resolved from the record of annual shell growth. A strong negative correlation exists between growth increment size and yearly mean water temperature.

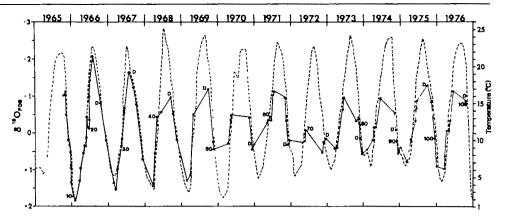

Live specimens of S. solidissima were collected from two localities off coastal New Jersey in the Middle Atlantic Bight, from water depths of 10 and 45 m. Growth increment analyses were performed whereby yearly changes in shell growth height were corrected for ontogenetic growth trends^{11,12} by dividing the measured shell height by the expected growth predicted using the Van Bertalanffy curve as described by Caddy and Billard¹³. This treatment yields a standardized index that can be compared among individuals of any size (age)¹¹. Between 7 and 23 isotopic samples of aragonite powder were secured from each annual growth band by microdrilling or filing of the outer shell layer. The inner layer was avoided to eliminate potential isotopic effects due to shell dissolution and reprecipitation. Annual dark growth increments in the outer layer provide reference points to differentiate successive years' of growth and to prevent sample overlap¹¹. Stable isotopic analyses were performed according to established procedures14 (all isotopic data are given in δ notation as the % enrichment or depletion relative

to the PDB carbonate standard¹⁵). A total of 150 separate isotopic analyses were made for an 11-yr period (1965-76) from the inshore 10 m specimen (INS no. 1), and for the calendar year 1966 in two offshore specimens from 45 m water depth (OFF nos 3, 5). The stable isotopic data sets for the calendar year 1966 were compared with surface and bottom temperature and salinity data available for the collection area^{11,16,17}. The exact year of growth could be determined if the collection date was known and the sclerochronological analysis of each shell^{9,11} performed.

The 11-yr isotopic time series from the 10-m site exhibits a regular periodicity and confirms that the δ^{18} O of the outer shell layer of INS no. 1 monitors the record of changing seasonal water temperature but not in a linear fashion (Fig. 1). The yearly isotopic amplitude (Δ^{18} O) decreases steadily from 1965 to 1972 and increases again from 1972 to 1976. The Δ^{18} O values have a maximum range of 3.8% during the first year of growth (1966). A straightforward interpretation of the isotopic range in terms of seasonal contrast would suggest wrongly that a steady decrease in seasonal contrast occurred from 1965 to 1972, with the seasonal amplitude increasing in years 1973-77. This interpretation is not supported by historical oceanographic data for the Middle Atlantic Bight 16,17. Shell growth in S. solidissima is apparently inhibited, but not totally stopped, during years with unusually warm mean sea surface temperatures (MSST) (>12.5 °C), and the observed yearly Δ^{18} O is reduced. During 1972, for example, when MSST was 13 °C, the Δ^{18} O values would suggest a seasonal contrast of <5 °C and unusually warm winter minimum and cold summer maximum temperatures (Fig. 1). Sclerochronological analysis of INS no. 1 revealed that the addition of shell height was maximum during the first year of growth and decreased almost exponentially until the eighth year of growth when a slight increase occurred again. Jones¹¹ had previously demonstrated that the size of annual growth increments in populations of S. solidissima are highly correlated with yearly mean sea surface temperatures. Shell growth conditions are apparently most favourable during years which have generally cooler water temperatures (MSST < 12.5 °C). A plot of the yearly isotopic amplitude (Δ^{18} O) versus a standardized growth index and mean sea surface temperatures (Fig. 2) reveals a similar relationship. The yearly isotopic range (Δ^{18} O) is negatively correlated (r =-0.77) with MSST and shows a strong positive correlation with the growth index (r = 0.79). Δ^{18} O values are therefore large and closer to the annual isotopic amplitude expected from the seasonal temperature contrast when MSST conditions are favourable to growth (Fig. 1). Periods of abnormally low growth thus best explain the diminished Δ^{18} O values. The Δ^{18} O record is, therefore, best interpreted as a function of MSST, and not as a measure of the annual temperature contrast or seasonality except possibly in optimum years of growth. The significant correlations in Fig. 2 suggest that the $\Delta^{18}{\rm O}$ values may be used to estimate the MSST of the Middle Atlantic Bight to within better than 0.5 °C.

It is desirable, therefore, that growth increment analyses be done concomitantly with detailed stable isotopic analyses of molluscs to interpret seasonality information from mollusc growth records properly. Even though the δ^{18} O at the outer shell margin of a particular mollusc may seem to reflect the approximate season that a specimen is collected, the isotopic amplitude cannot be strictly interpreted in terms of seasonality. The Δ^{18} O in particular species must be interpreted in the context of the growth history of the particular mollusc as was emphasized as early as 1953 (ref. 3). In the use of S. solidissima, we are fortunate that calibration of the Δ^{18} O, growth increments and seasonality can be made before investigation of fossil specimens. Once this calibration is made, it should be possible to decipher quantitatively important properties of continental shelf waters using isotopic and sclerochronological studies of fossil specimens. Although it is not possible to use S. solidissima to obtain a time series of seasonality, the mollusc may have the potential for recording the seasonal temperature amplitude on

Fig. 1 Oxygen isotope signal (solid line) for 11 yr of growth in a specimen of Spisula solidissima (INS no. 1) collected alive from a depth of 10 m on the Mid-Atlantic Bight off New Jersey. The dashed line corresponds to the monthly mean sea surface temperature for 1965-76 at the collection site. Isotopic data within a given year can be plotted knowing the growth rate of the specimen and the approximate position of the 'dark' growth increment which is laid down during the late summerearly autumn months 11,12,18.

the continental shelf. A test of this can be seen in Fig. 3 where the δ^{18} O signal for the year 1966 from INS no. 1 is plotted relative to the record of sea surface temperature (SST). The δ^{18} O data yield two types of information: (1) that the magnitude of the seasonal temperature contrast was accurately tracked; (2) that shell growth was continuous but varied systematically throughout the year in the following manner. Growth rates were most rapid during late spring-early summer (March-June).

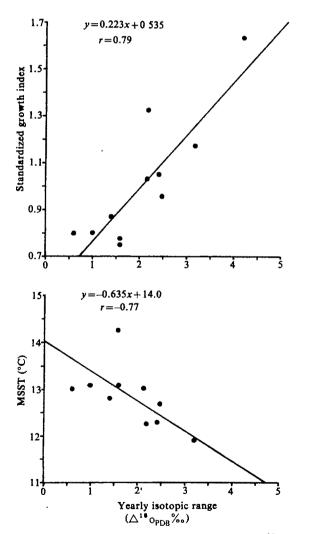

Fig. 2 The relationships of the yearly isotopic range (Δ^{18} O %) with the standardized growth index 11,12 and yearly mean sea surface temperatures (MSST) for 11 yr of growth in S. solidissima (INS no. 1). The best fit lines from linear regression analysis are also shown. The standardized growth index is computed by dividing the measured shell height by the expected growth using the Van Bertalanffy growth curve $^{11-13}$.

·d.

In July, growth slowed but decreased to a minimum during the SST maxima in August through October, when spawning and deposition of the characteristic dark increment occurred. Shell growth then increased again as SST cooled in October through December. This confirms the annual cycle in shell growth that has been quantitatively defined through biweekly observations of living S. solidissima populations from this region of the continental shelf ^{12,18}.

To determine whether these results could be used to differentiate the thermal structure on the continental shelf off New Jersey, the detailed δ^{18} O record for the year 1966 in INS no. 1 (10 m) was compared with that of two specimens collected live from 45 m water depth (OFF nos 3, 5) (Fig. 3). During January to April-May, the 10 m and 45 m specimens have identical δ^{18} O signals. From May to September, the 10 m and 45 m records clearly diverge as the surface waters continue to warm and the temperature gradient increases to a maximum in August. As the surface and 45 m water temperatures begin to converge in October to January, so do the δ^{18} O values of the inshore and offshore specimens. These trends lead us to believe that the isotopic records of these specimens are accurately monitoring seasonal contrasts in the surface waters as well as the seasonal development and breakdown of the thermo-cline between the inner and middle shelf¹⁹. As fossil specimens of S. solidissima which grew at different depths may be differentiated on the basis of their shell morphology and growth curves¹², it may be possible to reconstruct the thermal stratification along the continental shelf from fossil shells.

A detailed sclerochronological and stable isotopic study of annual growth increments in S. solidissima collected live has enabled us to establish confidence limits about the use of mollusc isotopic data in palaeoseasonality studies. Sclerochronological analysis enables optimum years of shell growth to be identified. Although the annual isotopic signal (Δ^{18} O) is qualitatively recorded in all years of growth, the magnitude of the Δ^{18} O in all years is not linearly related to the seasonal sea-surface temperatures. The first years of growth in S. solidissima seem to yield the best potential for quantitatively determining the seasonal contrast. It is possible, therefore, to use the isotopic data in S. solidissima to monitor successfully the development of the thermocline between the inner (10 m) and middle (45 m) continental shelf when the growth histories of the mollusc shells are understood. The carbon isotopic record of S. solidissima may also be utilized to decipher seasonal productivity and/or water mass stratification²⁰. Thus, calibration of the isotopic signals of molluscs like Spisula within a physical and biological framework may provide a powerful means to reconstruct the palaeo-oceanographic history of temperate continental shelves, especially during the Plio-Pleistocene for which numerous fossil deposits are available. Such valuable palaeoclimatic information has hitherto been unavailable from temperate continental shelf areas, and only possible where corals are present. Due to the thermal tolerances of mollusc species, however, caution may be required in palaeoseasonality studies of other mollusc species.

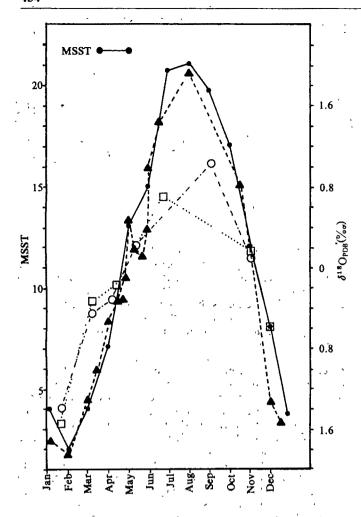

Fig. 3. A comparison of the seasonal change in monthly MSST for 1966 and the oxygen isotopic composition (δ^{18} O %) of the same year of growth in Spisula from water depths of 10 m (INS no. 1 ▲) and 45 m (OFF nos 3 O; 5 □). The isotopic data are plotted knowing the growth rates of the individual specimens and the position of the 'dark' growth increment which is laid down during the late summer-early autumn months 11,12,18.

The analytical work of this research was supported by the NSF. This is contribution no. 441 of the Belle W. Baruch Institute for Marine Biology and Coastal Research of the University of South Carolina. We thank Patricia Kelly and Kitty Harper for typing the manuscript.

Sedimentary record of rainfall variations in a sub-humid lake

Brian Rippey

The New University of Ulster, Limnology Laboratory, Traad Point, Magherafelt, Co. Derry BT45 6LR, UK

The physical, chemical and fossil characteristics of lake sediments are frequently used to study environmental processes and change within a lake, in the lake catchment and over a wider area. Analysis of sediment dry weight variations in a 1.3-m core from a lake, Dayat Afougach, in Morocco suggests that they record both seasonal and annual rainfall variations and the associated catchment erosion and lake sedimentation processes. If this is a common feature of certain lake sediments then these lakes may prove to be a source of information about changing precipitation patterns in areas where climatological records are not available, as well as providing information on changing sediment yields from their catchments.

Dayat Afougach (31°21' N, 5°07' W) is a 32 hectare eutrophic lake situated at an altitude of ~1,500 m in the Middle Atlas Mountains. The catchment area of the lake is roughly 1,400 ha and it is underlain by Mesozoic calcareous rocks1. The mean depth of the lake is around 6 m and it has an outflow but no perennial inflow. The lake is in a semi-arid region², but it has a fairly high annual rainfall (mean for 1927-49) of 1,100 mm (ref. 1) due to its high altitude. The climate corresponds to the Mediterranean winter-wet summer-dry sub-humid climate type (see Fig. 4a). A basic limnological description of the lake has been made by Gayrals3.

An undisturbed sediment core4 was taken at the deepest part of the lake in the south-east from 11 m on the 25 September 1979. There was no visible stratification of the calcareous sediment. It was sectioned at 1 or 2 cm intervals and the sediment dry weight found after drying to 105 °C. The sediment was rendered soluble by HF-HClO4 digestion⁵ and organic content estimated by loss on ignition⁶. Metal concentrations in the digests were determined by atomic absorption spectrophotometry, phosphorus colorimetrically and the precision of the results estimated by duplicates. The standard deviations for seven duplicates are 16 mg Ca per g, 3 mg Mg per g, 0.3 mg Na per g, 0.3 mg Fe per g, 0.06 mg P per g, 5 µg Mn per g, 2 µg Cu per g, 6 µg Zn per g, 15 µg Pb per g and loss

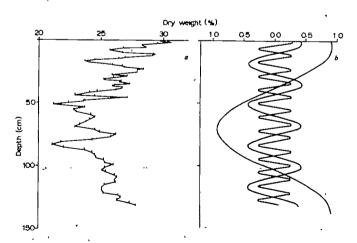

Fig. 1 a, The variation of sediment dry weight with depth in Dayat Afougach. b, The three Fourier harmonics, first, fourth and eleventh, which describe the dry weight behaviour in a The scale indicates how much each harmonic causes the dry weight to depart from its mean value of 25.4%.

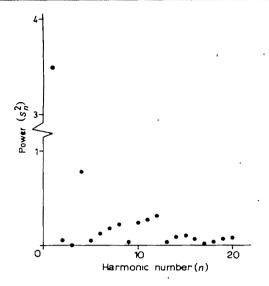

Fig. 2 The Fourier power spectrum of the dry weight results.

on ignition 1.3%. The dry weight results and annual rainfall totals from 1958 to 1979 for Ifrane, 23 km south-west of Afougach⁸, were subjected to Fourier analysis⁹.

The variation of sediment dry weight with depth (Fig. 1a) shows repetitive patterns and the Fourier power spectrum is shown in Fig. 2. The first harmonic accounts for 48.5% of the variance and has a wavelength of 131 cm, the length of the sequence. The sequence is too short to provide any evidence for a repeating unit of this wavelength. This harmonic only describes the general trend of increasing and decreasing values. An F-test shows the fourth harmonic accounts for a significant (0.005 < P < 0.01) amount of the variance (11.0%). It has a wavelength of 33 cm. The sixth, seventh and eighth harmonics, even taken as a group, are not significant (0.05 < P < 0.10). The tenth, eleventh and twelfth harmonics together make a significant contribution to the variance (0.005 < P < 0.01) and account for 11.9%. They have wavelengths of 13, 12 and 11 cm, respectively, and so with a wavelength around 12 cm account for the smallest scale repeating pattern in the dry weight results (Fig. 1a). Decomposed eleventh, fourth and first harmonics are shown in Fig. 1b. The contribution of the fourth harmonic is best seen when it is in phase with the eleventh harmonic at the pronounced dry weight minima around 15, 50, 83 and 120-cm depth. Two lines of evidence indicate that these dry weight patterns reflect rainfall variations.

The first concerns the smallest scale pattern, harmonics 10/11/12. This has a wavelength around 12 cm and is probably caused by an annual sedimentation cycle. The sediment accumulation rate would then be around 12 cm yr⁻¹. Three pieces of evidence support this interpretation. First, Wilson¹ has shown that there is a strong relationship between monthly sediment yield and monthly rainfall in catchments with a Mediterranean type climate. Assuming that the sediment has a larger particle size during the periods of higher yield, then the variation in monthly rainfall over a year (see Fig. 4a) could cause the smallest scale dry weight pattern by controlling the grain size of the allogenic sedimentary inputs and hence the dry weight^{11,12}. During the wetter months, especially those following the dry season¹⁰, the allogenic inputs would be coarser than during the drier months and would produce the sediment layers of higher dry weight. Second, the relationships of organic content, sodium, magnesium and iron concentration to dry weight (Fig. 3) also indicate that the dry weight variations are due to particle size variations. Organic content and sodium and iron concentration are higher in clay-sized sediments 13-15 and magnesium is frequently higher in the silt fraction 15,16, so the dry weight axis in Fig. 3 corresponds to particle size. None of the other elements determined (Ca, P, Mn, Cu, Zn, Pb) show

a significant relationship with dry weight. That the calcium concentration is constant suggests that the seasonal precipitation of calcium carbonate is not responsible for the patterns observed. Third, the implied accumulation rate of around 12 cm⁻¹ is reasonable in this environmental setting. Around 1-22.5 cm yr⁻¹ have been found in reservoirs with varying catchment size in the drier areas of the USA^{17,18} and a rough sediment yield from the catchment of around 900 tonnes km⁻² yr⁻¹, calculated assuming the accumulation rate, a mean sediment wet density of 1.25 g cm⁻³, no losses through the outflow and even sedimentation, is also reasonable in this environmental setting. Sediment yield is very variable but

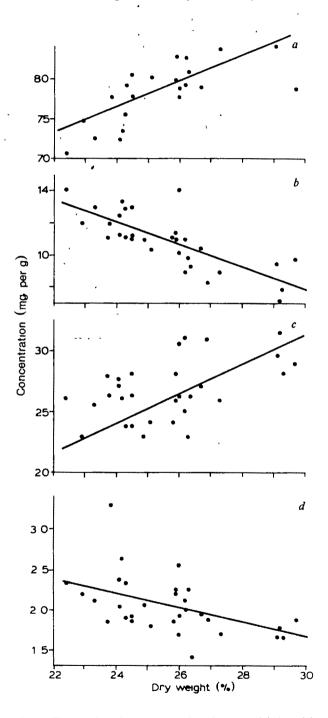

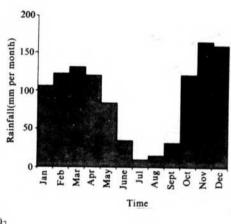

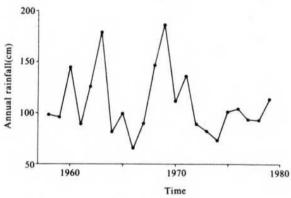

Fig. 3 The relationships between mineral content (a), iron (b), magnesium (c) and sodium (d) concentration and sediment dry weight in Dayat Afougach sediment. a: % mineral = 40.7 + 1.5 wt%, n = 23, $r^2 = 0.38$, 0.001 < P < 0.01. b: mg Fe per g = 28.8 - 0.698 wt%, n = 31, $r^2 = 0.57$, P < 0.001. c: mg Mg per g = 9.9 + 0.659 wt%, n = 31, $r^2 = 0.25$, 0.001 < P < 0.001. d: mg Na per g = 4.4 - 0.091 wt%, n = 31, $r^2 = 0.24$, 0.001 < P < 0.01.

around 600 and 700 tonnes km⁻² yr⁻¹ are suggested (ref. 19 and ref. 20 respectively) for this setting. The dry weight results in Fig. 1 show that, although the mean distance between peaks of the smallest scale pattern is around 12 cm, the distance varies from 8 to 18 cm. This behaviour appears to be accounted for by some of the harmonics on either side of 10/11/12, especially 7, 8 and 15, and may be due to annual variations in sediment yield from the catchment. Also, the dry weight-depth profile becomes damped and rounded below 100 cm. This may be due to compaction and to the 2-cm intervals used in sectioning the core at this depth. However, overall the three pieces of evidence suggest that the smallest scale repeating dry weight pattern reflects seasonal rainfall variations.

The second line of evidence suggests that the other two components of the dry weight variation reflect annual rainfall variations. Annual rainfall totals for Ifrane from 1958 to 1979 are shown in Fig. 4b and their Fourier power spectrum in Fig. 4c. The sequence is too short to provide reliable evidence that the third harmonic, with a wavelength around 7 yr, is a real environmental feature. This harmonic does, however, describe the decreasing rainfall in the early 1970s followed by a recovery, a pattern that was found over the whole of North Africa2 Assuming the 12 cm yr⁻¹ accumulation rate, then the low sedi-

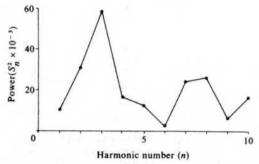

Fig. 4 a, The variation of monthly rainfall at Ifrane based on results from 1927 to 1949. b, The variation of annual rainfall at Ifrane from 1957 to 1979. c, The Fourier power spectrum of the annual rainfall at Ifrane from 1957 to 1979.

ment dry weight values between 50 and 90 cm, described by the first harmonic, correspond to the years 1971-74. Thus the general trend of decreasing and increasing sediment dry weight (Fig. 1a and first harmonic in Fig. 1b) reflects the trend of decreasing and increasing annual rainfall at Ifrane in the 1970s (Fig. 4b). The seventh and eighth harmonics in the Ifrane rainfall results have wavelengths of 2.9 and 2.6 yr. Having a wavelength <3 yr this component is reflected in the dry weight results by the fourth harmonic, which, assuming a 12 cm yr accumulation rate, corresponds to a wavelength of 2.8 yr. This, on average, just less than 3 yr rainfall cycle is probably part of the widespread quasi-biennial oscillation of many meteorological properties, including rainfall^{21,22}. The quasi-biennial oscillation has also been found in lake varves and tree rings23. That the fourth and eleventh dry weight harmonics are in phase (Fig. 1b) also supports the suggestion that the fourth harmonic corresponds to year to year variations.

The above evidence, although indirect, does provide a coherent picture of sedimentation in Dayat Afougach greatly influenced by rainfall variations. Establishing the accumulation rate directly by sediment dating and particle size analysis is, nevertheless, desirable to increase the reliability of the interpretation. Unavoidable loss of the core prevented particle size analysis being carried out. The alternate sediment layers of different chemical constitution and particle size in Afougach may be termed seasonal rhythmites and these have been found in other lakes^{24,25}, including semi-arid ones¹⁷. The seasonal rainfall variation at Afougach seems to provide the periodic variation in allogenic sedimentary input. Although annual variations in the flood events in another lake were found to be recorded in the sediment dry weight profile18, whether the calcareous nature of the Afougach sediment is important in allowing rainfall variations to be recorded is not known at

present. However, as the monthly sediment yield from catchments in areas with seasonal climates is dependent on rainfall10, sediment dry weight results may be a source of rainfall information in such areas, especially where there is little physical or biological mixing of the sediment.

I thank the other members of the group which visited Morocco in 1979, Roger Flower, Bob Nash, Alan Perrott and Doug Radford. Also, The New University of Ulster, The Royal Society, British Museum (Natural History), British Association for the Advancement of Science and the Royal Geographical Society for supporting the fieldwork and Ben Saied for his help in Morocco.

Modern archaeomonads indicate sea-ice environments

James G. Mitchell & Mary W. Silver

Marine Sciences Program, Center for Coastal Marine Studies, University of California, Santa Cruz, Santa Cruz, California 95064, USA

Diatoms, radiolarians, silicoflagellates, ebridians and archaeomonads are the primary groups of pelagic organisms in siliceous marine deposits, with only the archaemonads regarded as being absent from modern oceans and sediments. They remain a poorly known group of siliceous nanofossils in Cretaceous to Upper Tertiary marine sediments. We present here the first report, from any modern oceanic environment, of pelagic cysts that conform to the descriptions for Archaeomonadaceae. These cysts occurred in seawater, sea ice and marine-surface sediments, demonstrating the group is still extant. Furthermore, their distribution in modern sediment suggests they may be useful guide fossils for sea-ice environments as they occur abundantly only in polar or near-polar water where sea ice is present. Few other microorganisms seem to have such a close and exclusive association with sea ice, thus archaeomonads deserve increased attention as indicators of ice conditions for deep-water marine environments.

Small (7-20 µm) siliceous cysts found as minor constituents of many Upper Cretaceous to Pleistocene sediments, archaeomonads dominate few sedimentary assemblages^{1,2}, and thus their environmental affinities are poorly known. First described as a taxonomic group^{3,4}, archaeomonads are generally considered to represent resistant stages in the life histories of unknown or extinct marine chrysophytes, as they closely resemble the statocysts produced by freshwater chrysophytes⁵ Both archaeomonads and chrysophyte cysts are siliceous spheres possessing a single pore that is usually surrounded by a flange. Surfaces vary from smooth to spiny and are important taxonomic features in both taxa. Pelagic chrysophyte cysts have been reported from oceanographic surveys in the Weddell Sea10 and other areas11, but little or no taxonomic, descriptive or morphological information is given in these reports, making it impossible to determine whether the cysts belong to the Archaeomonadaceae or some other group such as those described by Silver et al. 12. Moreover, previous studies have relied on light microscopic examination of material, but careful descriptions of the diagnostic features of these nanoplanktonsized organisms require scanning electron microscopy (SEM).

Fifty-three water samples were obtained from a 10,000-km² area centred around 74°27′S, 37°53′W during the 1978 International Weddell Sea Oceanographic Expedition (IWSOE)¹³. The samples were taken at depths of 2–108 m; temperatures of –1.844 to –1.697 °C; oxygen concentrations of 6.85–8.79 ml per l, salinities of 34.01–34.94‰, and bottom depths of 377–1,982 m. All samples were taken at least 50 km from land or glacier in a water column averaging 500 m in depth. Water samples were filtered through Nuclepore filters (0.4 µm pores) and oven dried at 50 °C. This sample processing method destroys cellular components, making it impossible to study the vegetative cells associated with cyst hard parts, but leaves skeletal material clean and unharmed.

To prepare the filtered specimens for SEM, filters were coated with gold and examined using a JEOL JSM2 scanning electron microscope. To determine the wall composition, individual archaeomonads were analysed by X-ray fluorescence in a Cambridge S-180 SEM with an ETEC EDAX attachment. Counts were made across filters during routine SEM using transects of known area.

Twenty-three of the Weddell Sea water samples examined contained archaeomonads. Their average abundance was $1.4 \times 10^3 \, \mathrm{I^{-1}}$ in the seawater samples, (s.e. 2.8×10^2 , the maximum was $9.4 \times 10^3 \, \mathrm{I^{-1}}$). Archaeomonads were found in 20 out of 29 samples from 0 to 55 m and in 3 out of 24 samples from 55 to 110 m. Archaeomonads abundance decreased significantly with depth (P < 0.01). Four species were found in the Weddell Sea water column, Archaeomonas areolata, A. formosa, A. reticulosa and Litheusphaerella spectabilis. The X-ray analysis confirmed that specimens identified as archaeomonads possessed walls of silicon.

Additional records of archaeomonads in water samples were obtained from a search of our data files on epipelagic organisms found in the central California Current region and from a 1,650-m water sample (provided by A. Alldredge) from the same area. These records indicate that archaeomonads occurred in two locations from the central California Current at 35°70′ N, 123°67′ W, 50 m and 32° N, 118° W, 1,650 m (M.W.S. unpublished data). Although very rare in these samples, two different species were present, A. mangini and A. striata.

Four sea-ice samples were taken from the same area as the Weddell Sea water samples, one during the 1978 IWSOE and

three during the 1980 IWSOE. After the ice was washed and melted, the ice microorganisms were prepared in the same way as those from the water column. The 1978 sample was quantitatively prepared and counted, whereas those from the 1980 season were not; thus the 1980 material provides only qualitative data. Archaeomonads were present in all four samples of ice, and they occurred in densities of $13 \times 10^3 \, l^{-1}$ in the 1978 material and also were abundant, relative to diatom frustules, in the 1980 samples. Four species were found in Weddell Sea ice from the two years, A. areolata, A. formosa, A. mangini and

Thirty-six samples of surface marine sediment were examined (Table 1, Fig. 1) from areas throughout the world ocean where siliceous sediments are presently being deposited14. Twenty-five sediment samples were obtained from the Deep Sea Drilling Project repository, and 10 from the core library at Scripps Institution of Oceanography. The remaining sample was from a gravity core taken in the Weddell Sea (64°03' S 61°39' W). Thirty-one sediment samples range from Upper Pleistocene to Recent; three sediment samples are Pliocene, and two samples were dated as no older than the Pliocene (Table 1).

Cysts were obtained by suspending sediment aliquots in vials of distilled water, dispersing the slurry using a vortex mixer, and allowing the coarser fraction to settle for 5-7 min after which the upper third of the water was decanted, filtered and the filter treated for SEM. To avoid bias in the results, the samples were processed so that during the examination we did not know the origin of the sediment.

Archaeomonads were found in 6 out of the 36 sediment samples examined (Table 1). Five of the six samples were from south of the Antarctic Circle. One came from the Weddell Sea, four from the Ross Sea and one sample from the Western Bering Sea (55°33' N, 171°38' E). Six species of archaeomonad were found in the Ross Sea sediment samples, A. areolata, A. formosa, A. mangini, A. reticulosa, A. sphaerica and L. spectabilis. Two species were found in the Weddell Sea sediment sample A. areolata and A. striata. As the samples without archaeomonads were searched as carefully as those containing the cysts, we think the lack of these specimens in the other samples indicates a real decrease in their abundance outside the areas of sea ice.

The discovery of significant numbers of archaeomonads in sea ice, water underlying the ice, and surface sediments underlying areas often covered with ice (Fig. 2) represents the first finding of archaeomonad-like cysts in the modern ocean. Their appearance in these samples establishes continuity from early Pleistocene archaeomonads to Recent marine chrysophyte cysts, and the modern distribution implies a distinct association between modern archaeomonads and sea ice. Although these cysts occurred in low numbers elsewhere, as shown by their presence in the California Current water samples, they were insufficiently abundant to contribute to underlying sediments. Similar sea-ice associations have been reported by Sancetta¹⁵ who found particular abundance ratios of diatom species in sediments associated with overlying ice and hydrographic conditions. Although chrysophytes occur throughout the world's oceans, they may, like their freshwater relatives9, produce a significant number of cysts only in extreme environmental conditions.

The distribution and abundance data presented here suggest that, in response to sea-ice formation, significant numbers of chrysophytes form the resistant cysts described previously as archaeomonads. This response to sea-ice coverage, which is a limited stimulus on a global scale, may explain why archaeomonads are absent or rare in most siliceous sediments and suggests other locations where they might be found. The association of archaeomonad cysts with polar sea ice, indicates they may be useful palaeoclimatological indicators.

We thank D. Ringo for encouragement and suggestions throughout the project. L. LaPorte, C. Moore, P. Bolt, E. Chu, and E. Diaz de Leon provided helpful comments. J. Nowell, M. Gowing and C. Zenker provided valuable discussion and

help with the SEM, M. Gowing took micrograph Fig. 2c. We thank D. Adam for the X-ray analysis and for preprints. W. Reidel provided the Weddell Sea sediment sample. T. Wood and T. Walsh provided samples. We also thank T. Foster for access to samples, equipment and ship time. J.G.M. thanks A. and C. Pert. Funding was provided by a UC President's Undergraduate Fellowship, other internal awards and NSF grants DPP 75-14936, DPP 78-07797 and DPP 80-20616.

Flowers are seldom preserved in an identifiable condition. The limited knowledge of floral structure of ancient flowering plants makes comparisons with living plants difficult, as floral structure is the basis for classification of the angiosperms. When found, fossil flowers contribute considerably to our understanding of the evolution of flowering plants¹⁻⁶. The flowers described here were recovered from Upper Eocene deposits near Anglesea, Australia. They are tetramerous, unisexual, male, with 16 stamens and tricolporate pollen. These flowers, and associated ebenaceous leaves, are the oldest known remains of the Ebenaceae from Australia.

The Ebenaceae, the persimmon and ebony family, represents one of the small group of families of angiosperms whose name is not based on a currently valid generic name. The familial name was derived from the pre-Linnaean Ebenus Rumphius. Generic limits within the family are the subject of some controversy. As many as nine genera, including the widely used Maba Forst., Royena L, and Tetraclis Hiern have been recognized, but a more recent consensus has included all but one of these, Euclea Murr., in Diospyros L, the currently valid type genus⁷⁻⁹. Of the 400-500 species ascribed to the Ebenaceae, only 14 may be attributed to Euclea, with the remainder in Diospyros sensu lato. Generic segregation was rejected due to the great uniformity of floral structure throughout Diospyros s.l.

The Ebenaceae is pan-tropical, with a few temperate outliers such as the American persimmon, Diospyros virginiana L. By far the greatest diversity is found in the Indo-Malaysian region. No recent synopsis of Australian species is available, but published regional floras indicate that 15 species of Diospyros occur

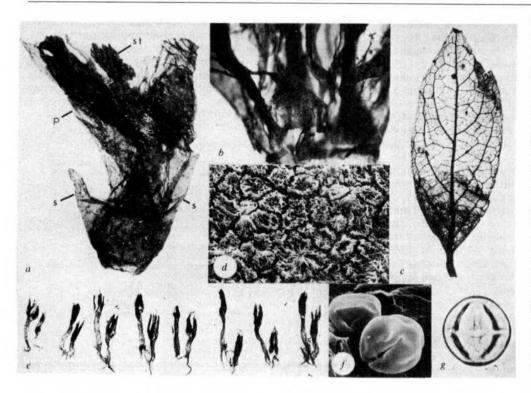

Fig. 1 Fossil flowers and leaves from the Eocene of Anglesea, Australia. a, Complete flower showing sepals (s), petals (p) and stamens (st), specimen number A-340 in the University of Adelaide Paleobotanical Collection (×7) b, Rudimentary gynoecium, surrounded by filaments of stamens, at centre of flower, A-342 (×25). c, Fossil leaf found in association with flowers, AM-243 (×1.4). d, Scanning electron micrograph of abaxial surface of leaf; note cuticular thickenings over epidermal cells and the overarching papillae that obscure the stomata, e, Stamens AM-260 $(\times 365).$ removed from a complete flower, arranged in their relative position within the flower; note that stamens occur in pairs with one short and one long filament, A-341 (×5). f, Scanning electron micrograph of a fossil pollen grain, in polar view, preserved within an anther; note the smooth appearance of the exine (×450). g, Light micrograph of a fossil pollen grain from an anther; equatorial view showing tricolporate structure (×450).

in Australia^{10,11}. Although many stellate calyces and entiremargined leaves of late Cretaceous, and Tertiary age have been assigned to *Diospyros*, in few instances are features well enough preserved or of sufficient diagnostic value for positive identification. The fossil record for leaf and especially floral structure of the Ebenaceae is scant.

The fossils described here were found in clays overlying the Eastern View Coal Measures exposed at the Alcoa power station at Anglesea, Victoria. The sequence includes coarse to fine cross-bedded sands with lenses of carbonaceous clay, and has been dated as late Eocene^{12,13}. Most of the ebenaceous fossils occur in a single clay lens in association with a diverse leaf flora of over 40 taxa. Previous studies of clay lenses about 8 m higher in the sequence have revealed the presence of Casuarinaceae, *Bowenia*, and a zamioid cycad, *Pterostoma* Hill¹⁴⁻¹⁶.

Approximately 100 flowers have been recovered. All that remains of most of them are four-parted calyces whose sepals are fused in their basal third. Total sepal length is 3-5 mm and width is ~ 2 mm, and their shape is roughly triangular. Sepals possess numerous simple hairs on both inner and outer surfaces. The corolla and sexual organs seem to have been lost from the calyx as a unit. This is supported by the presence of such units in the macerates. Complete flowers and isolated corolla units contain only stamens and were strictly unisexual, male flowers. A small, bulbous structure at the centre of a few flowers represents an aborted gynoecium (Fig. 1b).

The actinomorphic corolla consists of four contorted petals that alternate with the sepals. The petals are fused to just above the tips of the sepals, a distance of about 1/3 of their total length of 7–9 mm. Petals, like sepals, have unicellular, simple hairs, although hairs tend to be most abundant on the margins and abaxial midline.

The androecium consists of 16 stamens which are paired, each pair comprising one long- and one short-filamented anther (Fig. 1e). Each anther has four locules and dehisces by longitudinal slits. Bleaching of the fossil anthers often causes separation of the tapetum from the anther wall, freeing four pollenfilled pouches from each. The pollen is tricolporate, subprolate, and $\sim 30~\mu m$ in equatorial diameter (Fig. 1f, g). The grains have a smooth to slightly scabrate exine.

No female flowers have yet been recovered. However, the observed rudimentary gynoecia are sufficient to illustrate that the flower is hypogynous, with an ovary with more than one style. Unisexuality in flowering plants is commonly achieved by such incomplete development of one type of sex organ. The clustering of well-preserved fossil flowers may indicate that they are derived from one or a few individuals that grew very close to the site of deposition. Most living *Diospyros* are dioeceous, and a similar condition in the fossil species may explain the abundance of male and apparent lack of female flowers.

Floral and pollen morphology of the fossil flowers form a unique suite of characters found only in one extant family, the Ebenaceae. Favourable comparisons may be made with many extant species of *Diospyros* s.l. *Diospyros* is a closely knit genus with remarkably uniform floral structure. Although flowers are tri-, tetra-, to pentamerous, the general appearance of the unisexual flowers, with their calyx cup, connate and contorted petals, radial pairs of stamens, tricolporate pollen, and superior ovary, varies little. The presence of eight radial pairs of stamens in the fossil and in many tetramerous extant *Diospyros* is very unusual among flowering plants and in itself could be considered diagnostic. Only minor differences in shape and size of floral organs, and no significant structural differences, distinguish the fossil flowers from such living tetramerous species of *Diospyros* as *D. australis* Hiern.

Associated with the fossil flowers are leaves of more than 40 species of angiosperms. The commonest of these, currently represented by 45 complete individuals in our collection, is a

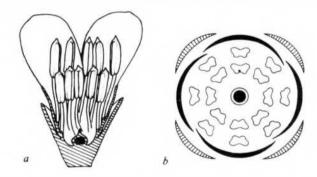

Fig. 2 a, Reconstruction of flower in median longitudinal section. b, Floral diagram.

highly variable taxon. It ranges in size from 4 to 110 mm in length and 2 to 60 mm in maximum width. Shape is equally variable, ranging from lanceolate to ovate to nearly orbicular. Venation is brochidodromous (Fig. 1c). These features are consistent with several extant Australasian species of Diospyros, but are by no means diagnostic of them. Of greater importance is the cuticular structure of these fossil leaves. The stomatal complexes are of the actinocytic type, with 4-6 irregular subsidiary cells. Each subsidiary cell produces a large papilla that overarches the guard cells. Cells of the lower epidermis possess extensive ridge-like thickenings of the cuticle (Fig. 1d).

Cuticular patterns on the abaxial epidermis of extant Diospyros are extremely diverse, ranging from nearly smooth (such as D. calycantha O. Schwarz), to striate or wrinkled, to ridged, to ornate, with large, frill-like accumulations of cutin (such as D. australis Hiern, D. macrocarpa Hiern). Due to intraspecific consistency of characteristic epidermal modifications, cuticular analysis is a valuable tool in identification and classification of both living and fossil plants. Cuticular thickenings, subsidiary cell arrangement, and over-arched stomata of the fossil leaves are similar to many extant Diospyros and fit easily within the range seen in the genus.

Of great significance is the occurrence of the same distinctive cuticular pattern on the fossil leaves and on the sepals of the fossil ebenaceous flowers. Flowers and leaves have not been found in organic connection. However, close association in the fossil flora, similarity of foliar and floral features to living Ebenaceae, and especially cuticular similarity of both organs indicate that the fossil leaves and flowers represent one taxon.

The evolutionary history of the Ebenaceae is unclear. There is a general consensus that the Ebenales was derived from the Theales, but the divergence has been significant 17,18. Many fossils (both leaves and fruits) have been ascribed to Diospyros. They are reported from North America, Europe, and Asia as well as Australia 19-22. Ettingshausen reported Diospyros leaf impressions and fruit casts from Australia²³. However, with no floral structure and no cuticles, his identifications are questionable. Similarly, serious doubt is cast on other reports of macrofossil evidence of the family. Ebenaceous pollen is not distinctive, and Palaeogene reports are unreliable. The flowers reported here are the earliest known identifiable floral remains of the Ebenaceae and the earliest well documented occurrence of the family in Australia.

As the Ebenaceae is pan-tropical, with the centre of diversity in Malaysia, it is tempting to believe that this might have been the region of origin. If this were true, the 15 extant Australian species would most probably have evolved from post-Miocene arrivals through New Guinea, since Palaeogene dispersal from South-east Asia to Australia would invoke excessive, if not incredible distances.

A Malaysian origin is opposed by the many species in Australia, South America, and Africa, and the Eocene fossils from Australia, which suggest that the Ebenaceae had a Gondwana origin with subsequent dispersal to the Malaysian region, possibly as late as the Miocene, through India and/or Australia. However, if some of the Laurasian fossils of early Tertiary age, in particular flowers assigned to Diospyros from the British late Eccene²², are correctly assigned to the Ebenaceae, the family may have already become very widespread by that time.

The Anglesea fossils also provide evidence that the floral features typical of many Ebenaceae—for example, tetramery, unisexuality, stamens in pairs and four times the number of corolla lobes, fused and contorted petals, and tricolporate pollen-were well established by Eocene times, and that selective pressures since that time have not been sufficient to alter them. Foliar features, too, were well advanced. Leaf architecture and the peculiar cuticular thickenings that characterize living Ebenaceae were present in the Eocene and were already associated with a typically ebenaceous floral plan.

Systems of angiosperm classification continue to be based, as they have since the time of Linnaeus, on floral morphology.

The validity of phylogenetic interpretations based on these systems is tested most critically by floral evidence from the fossil record. Within this framework, the importance of the discovery and analysis of structurally preserved flowers, such as those from Anglesea, is obvious.

Self-excitation of olfactory bulb neurones

R. A. Nicoll & C. E. Jahr*

Departments of Pharmacology and Physiology, University of California, San Francisco, California 94143, USA

The concept that neurotransmitter released from a neurone may feed back and influence the excitability of the same neurone has been suggested by a variety of evidence. Anatomical studies have shown that axon collaterals can arborize among the dendrites of the parent neurone¹⁻⁷, suggesting a direct feedback via axon collaterals. In addition, the dendritic release of dopamine from substantia nigra neurones has suggested that dopamine may exert a direct feedback inhibition of these neurones^{8,9}. Little electrophysiological evidence is available, however, to indicate that such a mechanism does exist. Based on intracellular recordings, Park et al. 10 have proposed a direct inhibitory feedback in the neostriatum, but a presynaptic mechanism was not entirely excluded. We have now found that blockade of synaptic inhibition of relay neurones in the olfactory bulb unmasks long-lasting depolarizing potentials which can trigger repetitive discharges. These depolarizing potentials result from direct feedback of dendritically released excitatory transmitter onto the same and neighbouring relay neurones. Such a process might contribute to epileptogenic neuronal discharge.

We have used the *in vitro* turtle (*Pseudemis scripta elegans*) olfactory bulb preparation¹¹⁻¹³. The bulb was hemisected to facilitate the placement of stimulating and recording electrodes. Microelectrodes (140-180 M Ω) filled with 2 M potassium methylsulphate were used to record intracellularly from mitral cells (the principal relay neurones of the olfactory bulb). Mitral cells could be activated synaptically by stimulating the olfactory

^{*}Present address Department of Neurobsology, Harvard Medical School, Boston, Massachusetts 02115, USA

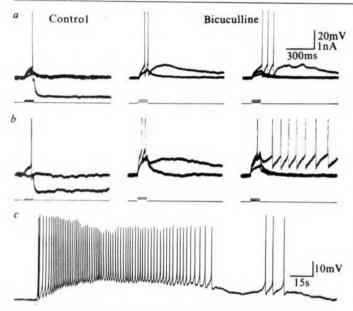

Fig. 1 Blockade of i.p.s.ps reveals depolarizing after-potentials. The superimposed oscilloscope records in this and the following figures show one or two traces with subthreshold depolarizing current pulses applied through the recording microelectrode and one trace with a suprathreshold pulse. The current trace is shown below the voltage trace. a, b Show two examples of the effect of bicuculline methiodide (BMI) (0.1 mM). The GABA antagonist had been present for 8 min during the second and third responses in a, and for 10 min in b. The cells often fired repetitively during the depolarizing after-potential. Resting membrane potential for cell in a is -57 mV and in b, -68 mV. Spikes in b are truncated. c Shows a pen record of a prolonged burst of action potentials elicited by a single 100-ms depolarizing current pulse. This cell had been exposed to BMI (0.2 mM) for 17 min. Resting membrane potential -52 mV. The calibration in a also applies to b.

nerves, antidromically by stimulating their axons or directly by passing depolarizing current pulses through the recording electrode. A bridge circuit was used so that the membrane potential could be monitored during the current pulses.

In the absence of an antagonist of γ -aminobutyric acid (GABA), action potentials evoked in mitral cells by the injection of depolarizing current were followed by inhibitory postsynaptic potentials (i.p.s.ps) (Fig. 1a, b) which result from the direct activation of the reciprocal dendrodendritic synapses between mitral and granule cell. Similar to the i.p.s.ps elicited by stimulating mitral cell axons 12-14, these directly activated i.p.s.ps are thought to be mediated by GABA12,13. Addition of the GABA antagonists, bicuculline methiodide or picrotoxin, to the superfusate blocked the hyperpolarizing i.p.s.p. and, in 40 of 46 cells examined, uncovered a prolonged depolarizing after-potential (DAP) (Fig. 1a, b) which was at times intense enough to trigger repetitive firing of the mitral cell (Fig. 1). In Fig. 1c, a single 100-ms depolarizing current pulse evoked a discharge lasting for ~3 min. We considered three possible mechanisms for this DAP. It could result from an increase in a sodium conductance which inactivates slowly, such as has been reported in cerebellar Purkinje cells¹⁵. However, unlike the Purkinje cell response, the mitral cell DAP was not blocked by the addition of a concentration of tetrodotoxin (TTX) (1 µM) sufficient to block the fast directly evoked action potential (n = 11) (Fig. 2).

Another process which could produce the DAP is a slow, voltage-dependent calcium conductance. The DAP is calcium dependent because in the seven cells examined it was blocked by the calcium antagonists cobalt (2 mM) or cadmium (0.5 mM), which also blocked the TTX-insensitive action potential (Fig. 2; see also refs 11-13). The calcium antagonists would also be expected to block the release of transmitter. If the DAP were a result of a voltage-dependent mechanism (whether calcium or sodium mediated) it should be aborted by hyperpolarizing

the membrane, as has been seen in other systems $^{16-18}$. However, injection of a hyperpolarizing current pulse through the recording microelectrode did not alter the duration of the DAP (n=6) (Fig. 3a) even when the hyperpolarizing pulse outlasted the DAP. This finding suggests that the DAP may result from feedback of excitatory transmitter released from the same mitral cell.

Another manipulation that might distinguish between a calcium conductance increase and a feedback of excitatory transmitter is the substitution of barium for calcium. Barium can readily pass through calcium channels (in some cases better than calcium19), but it substitutes poorly, if at all, for phasic evoked transmitter release²⁰⁻²³. We have tested the ability of barium to substitute for calcium in synaptic transmission in the olfactory bulb by recording the field potential evoked by the excitatory synaptic action of mitral cell dendrites on granule cell dendrites. We found that when synaptic transmission was blocked in a zero calcium Ringer, 3 mM barium was unable to restore transmission. However, switching back to normal Ringer containing 3 mM calcium quickly restored the synaptic potential. The effect of barium substitution on the DAP was examined in five cells. A typical result is shown in Fig. 3b in which the DAP was completely blocked while the amplitude of the TTX-insensitive spike was actually increased. The abolition of the DAP by barium substitution suggests that the DAP is mediated by the release of synaptic transmitter. Note that addition of barium to normal Ringer did not block the DAP13, indicating that barium is not a calcium antagonist for the release process, but rather fails to mimic the action of calcium. In light of the evidence presented above and because the DAP was not blocked by deleting axonal pathways with TTX, we suggest that mitral cell activation causes dendritic release of an excitatory transmitter which feeds back directly onto the same mitral cell.

Recent biochemical evidence strongly suggests that aspartate is the transmitter released from mitral cell axon terminals in the olfactory cortex²⁴. It is, therefore, reasonable to expect that aspartate is the transmitter released from mitral cell dendrites. We have found that iontophoresis of either glutamate or aspartate in the presence of GABA antagonists depolarizes mitral cells²⁵. α -Amino adipate (α AA), which antagonizes aspartate responses in other systems^{26,27}, decreased the depolarizing

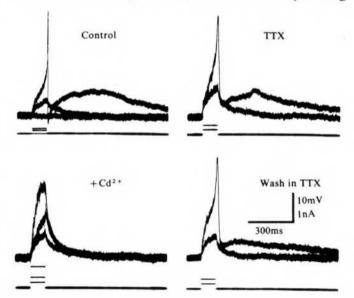

Fig. 2 The depolarizing after-potential is resistant to tetrodotoxin (TTX) but blocked by the calcium antagonist cadmium. The control record was obtained 10 min after switching to bicuculline (0.1 mM) (spike truncated). TTX (1 μM) was then superfused for 22 min and only slightly reduced the DAP. After exposure to cadmium (Cd²⁺) (0.5 mM) for 10 min, the depolarizing after-potential and the calcium spike were entirely blocked. Washing for 90 min (in TTX) restored the calcium spike and DAP. Resting membrane potential, -56 mV.

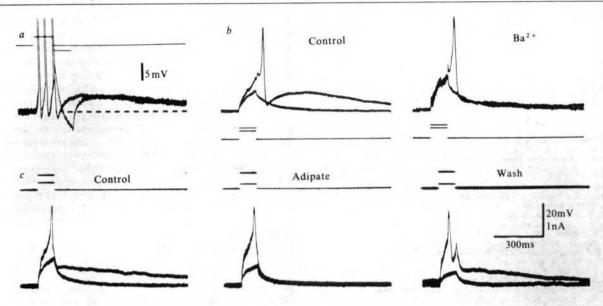

Fig. 3 Properties of depolarizing after-potential. In a, a hyperpolarizing current pulse applied immediately after a suprathreshold depolarizing current pulse did not diminish the DAP. The preparation had been bathed in BMI (0.1 mM) for 23 min. Resting membrane potential, -53 mV. The control record in b was obtained 30 min after switching to a solution containing TTX (1 μM) and BMI (0.1 mM). The record to the right was obtained 12 min after substituting 3 mM barium for calcium. Resting membrane potential, -57 mV. The control record in c was obtained 50 min after switching to a solution containing TTX (1 μM) and picrotoxin (0.2 mM). Adipate (1 mM) was then added to the superfusion medium for 15 min. The record on the right was obtained 24 min after returning to the control solution. Resting membrane potential, -62 mV. The calibration in c also applies to b.

effect of iontophoretic aspartate on mitral cells (not shown). We examined the sensitivity of the DAP to α AA in the presence of TTX so that we could use the calcium spike as a monitor of the specificity of α AA. The DAP was reversibly abolished by α AA (n=6), which had little or no effect on the calcium spike (Fig. 3c). The blocking effect of α AA, therefore, occurred after calcium entry. The i.p.s.p. in normal Ringer was also reversibly abolished by α AA.

After inhibition was blocked, antidromic action potentials were also followed by DAPs (Fig. 4b). The antidromic spike can be fractionated by passing a hyperpolarizing current pulse through the recording microelectrode, timed to occur when the antidromic spike arrives at the soma 12,13. Large current pulses blocked invasion of the soma-dendritic membrane, revealing a small action potential that probably resides in the initial segment^{28,29}. When only the initial segment was activated, the resulting DAP was small (Fig. 4b). However, when invasion of the soma-dendritic membrane occurred, a larger DAP resulted. This incremental increase in the amplitude and duration of the DAP is, therefore, due to activation of the soma-dendritic membrane. A depolarization could also be evoked by antidromic stimulation which was subthreshold for the axon of the impaled cell (Fig. 4a). These findings suggest that transmitter released from antidromically invaded mitral cells can diffuse to neighbouring mitral cells. Indeed, in the presence of GABA antagonists, mitral cells frequently fire spontaneous bursts of action potentials (Fig. 4c), suggesting the presence of synchronized activity.

Thus, in normal conditions an excitatory transmitter, probably aspartate, is released from mitral cell dendrites and activates receptors on the processes of granule cells. The ensuing depolarization results in the release of GABA from the granule cells back onto the same mitral cell. When the inhibitory half of the reciprocal synapse is blocked with GABA antagonists, the activation of olfactory bulb mitral cells is followed by an excitatory depolarizing potential instead of an i.p.s.p. The present findings indicate that this depolarizing potential results from the direct feedback of dendritically released excitatory transmitter onto the same mitral cells. The depolarization elicited by both subthreshold antidromic stimulation and in the presence of only an initial segment spike indicates that this phenomenon is not limited to single cells, but can involve an interaction of

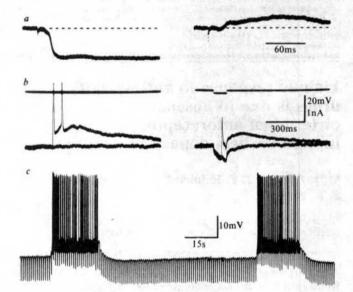

Fig. 4 Antidromic stimulation evokes depolarizing responses in the presence of GABA antagonists. The response on the left in a shows an i.p.s.p. to a stimulus below threshold for the axon of the impaled cell. The right-hand record was obtained 32 min after switching to a solution containing 0.2 mM picrotoxin. Resting membrane potential, -64 mV. The responses in b were obtained 12 min after switching to a solution containing 0.1 mM bicuculline methiodide. The record on the left in b shows the response to antidromic stimulation suprathreshold for the impaled cell (spikes truncated). The record on the right shows that when a hyperpolarizing current pulse blocked firing of the soma-dendritic membrane, the DAP was reduced in size but was still present. Resting membrane potential, -58 mV. c Shows spontaneous bursts of action potentials from the same cell illustrated in a, 47 min after switching to the picrotoxin-containing solution. The voltage gain in a is twice that in b.

a population of neurones, each contributing to the depolarization of its neighbours. In addition, excitatory recurrent collaterals could also contribute to this lateral spread of excitation³⁰. The prolonged depolarization which follows olfactory nerve stimulation in the presence of GABA antagonists^{13,31}

may also be due in part to similar excitatory feedback mechanisms. While the physiological significance of self-excitation, either via a dendritic or axon collateral pathway, is unclear, such a process might well contribute to epileptogenic burst discharge in other brain regions.

Unique response to antipsychotic drugs is due to absence of terminal autoreceptors in mesocortical dopamine neurones

Nicoll, R. A. Science 171, 824-826 (1971) Nowycky, M. C., Mori, K. & Shepherd, G. M. J. Neurophysiol. 46, 649-658 (1981)

A projection of dopamine (DA) neurones has been identified which runs from the rat midbrain ventral tegmental area to the cerebral cortex1. Relative to other cortical areas, the prefrontal cortex is enriched in DA^{2,3}, tyrosine hydroxylase³, DA uptake^{2,3}, DA-sensitive adenylate cyclase² and DA-responsive neurones4. Lesions of the prefrontal cortex or selective lesions of the prefrontal cortical DA innervation induce functional deficits, including detrimental effects on delayed response tasks, a difficulty in suppressing attention to irrelevant stimuli and a diminution in affective and social behaviour (for a review, see ref. 5). Recent studies have shown that this mesocortical DA system differs from other DA systems (such as the nigrostriatal and mesolimbic DA systems) in terms of drug responsiveness. For example, the acute administration of antipsychotic drugs (for example, haloperidol) greatly accelerates DA turnover in the nigrostriatal and mesolimbic DA systems through multiple sites of action, but only modestly accelerates mesocortical DA turnover. Following the chronic administration of moderate doses of antipsychotic drugs, tolerance to the effects of a haloperidol challenge dose is generally seen in the striatum and olfactory tubercle but not in the frontal cortex⁶⁻⁸. Similar results obtained in experiments involving primates have led to the suggestion that the frontal cortex may be the site of therapeutic

action of the antipsychotic agents^{9,10}. In light of the recent finding that rat mesocortical DA neurones lack terminal autoreceptors¹¹, we have investigated the possible role of nerve terminal DA autoreceptors in mediating the varied responses seen in different brain regions following acute and chronic antipsychotic drug treatment. The results, reported here, suggest that both the relatively small activation of the mesocortical DA system in response to a haloperidol challenge, and the lack of tolerance to haloperidol following chronic treatment, may be related to the absence of nerve terminal autoreceptors.

Male Sprague-Dawley rats (Charles River; 200-250 g) were injected intraperitoneally (i.p.) with either haloperidol (0.5 mg per kg) or vehicle for 28 days, as previously described¹². Some animals received a haloperidol challenge (1 mg per kg) or vehicle 60 min before decapitation. For experiments directly assessing DA autoreceptor function, other rats were withdrawn from haloperidol for 7 days before use. In other experiments, unilateral knife cuts of the medial forebrain bundle were performed under halothane anaesthesia 35 min before decapitation. The coordinates used were: 3,180 µm anterior to lambda; 500 µm lateral to the midline; 6,000 µm vertical from the dura¹³. From this position the knife was extended ~4 cm and lowered to the base of the brain. The striatum, olfactory tubercle and prefrontal cortex were dissected from the brain¹¹, and DA and dihydroxyphenylacetic acid (DOPAC) levels determined chromatography using liquid with electrochemical detection11,14

Acute haloperidol challenge dramatically increased both striatal and olfactory tubercle DOPAC levels (Fig. 1). In the prefrontal cortex, a much smaller but significant increase in DOPAC was seen after haloperidol challenge (Fig. 1). In parallel experiments, haloperidol challenge greatly accelerated the α -methyltyrosine-induced decline of DA in the striatum and olfactory tubercle, but not that in the prefrontal cortex (M.J.B. and R.H.R., unpublished). It has been previously demonstrated that the small haloperidol-induced increase in prefrontal cortical DA synthesis is totally prevented following the blockade of dopaminergic impulse flow¹¹. As mesocortical DA neurones lack nerve terminal autoreceptors, it has been

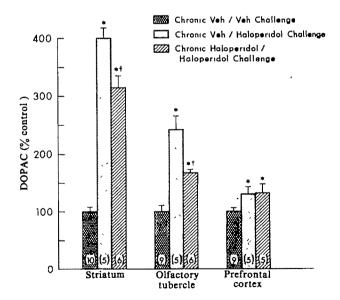

Fig. 1 Effects of acute and chronic haloperidol treatment on DOPAC levels in various brain regions. Animals were chronically treated with haloperidol or vehicle as described in the text. Haloperidol (1 mg per kg, i.p.) or vehicle challenge was administered 60 min before decapitation. The bars on the columns represent the s.e.m. and the numbers in the columns indicate n. Control striatal, olfactory tubercle and prefrontal cortical DOPAC levels were $1,092\pm86,1,004\pm96$ and 34 ± 2 ng per g respectively. *P<0.05 when compared with vehicle-treated animals, P<0.01 when compared with acute haloperidol challenge.

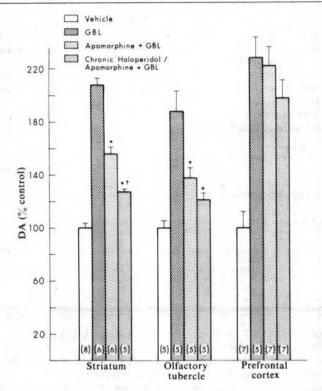

Fig. 2 Effects of chronic haloperidol treatment on DA autoreceptor sensitivity in various brain regions. Animals were chronically treated with haloperidol and withdrawn as described in the text. GBL (750 mg per kg, i.p.) was administered 35 min before decapitation. Some rats received apomorphine (0.25 mg per kg, i.p.) 5 min before GBL. The bars on the columns represent the s.e.m. and the numbers in the columns indicate n. Control DA levels in the striatum, olfactory tubercle and prefrontal cortex were $9,019\pm312$, $6,355\pm345$ and 86 ± 10 ng per g respectively. Chronic haloperidol treatment did not significantly alter DA levels (unpublished). *P<0.01 when compared with animals treated with GBL alone; $^{\dagger}P$ <0.05 when compared with the apomorphine-induced reversal of GBL in vehicle-treated rats.

suggested that the effects of haloperidol on this system are due solely to alterations in neuronal impulse flow¹¹.

Following chronic haloperidol treatment, significant tolerance to the DOPAC-elevating effect of a haloperidol challenge developed in both the striatum and the olfactory tubercle (Fig. 1). No change in the response to haloperidol was observed in the prefrontal cortex (Fig. 1). These results are in agreement with previous studies (in both rodents and primates) which have demonstrated the development of tolerance in the striatum, and in some cases limbic brain areas, with a lack of tolerance or even reverse tolerance in the frontal cortex⁶⁻¹⁰.

To examine the relationship between tolerance to haloperidol changes in autoreceptor sensitivity, a pharmacological method for eliminating dopaminergic impulse flow was used. Administration of γ-butyrolactone (GBL) reversibly blocks DA impulse flow, resulting in an increase in tyrosine hydroxylation and DA levels in nigrostriatal and mesolimbic DA systems similar to that seen after mechanical lesioning of these systems (for a review, see ref. 15). These changes have been proposed to result from a decreased DA autoreceptor activation secondary to the decreased amount of DA released into the synaptic cleft16. Direct-acting DA agonists prevent this increase in DA synthesis solely through the stimulation of DA nerve terminal autoreceptors^{11,12}. As previously reported, the GBL-induced increase in striatal and olfactory tubercle DA was partially reversed by an intermediate dose of apomorphine (Fig. 2). The increase in prefrontal cortical DA was unaffected by apomorphine pretreatment (Fig. 2), indicating the lack of mesocortical nerve terminal autoreceptors, as previously described11. Following chronic haloperidol treatment, an enhanced response to apomorphine, that is, DA autoreceptor supersensitivity, was directly demonstrated in the striatum (Fig. 2), confirming previous results ^{12,17,18}. The DA autoreceptors in the olfactory tubercle became slightly (but nonsignificantly) more sensitive, but no autoreceptor activity was revealed in the prefrontal cortex (Fig. 2).

To establish that the apparent lack of DA autoreceptors in the prefrontal cortex following GBL administration was not due to some unexpected effect of this drug on mesocortical neurones, autoreceptor function was assessed following the acute axotomy of the medial forebrain bundle (Fig. 3). Axotomy, like GBL, induced apomorphine-reversible increases in striatal and olfactory tubercle DA (Fig. 3), as previously reported 16,19,20. As expected, the axotomy-induced increase in prefrontal cortical DA was unaffected by apomorphine, providing additional evidence that mesocortical DA neurones lack terminal autoreceptors. The axotomy- and GBL-induced accumulation of prefrontal cortical DA (Figs 2, 3) are not a result of an acceleration of DA synthesis, but are presumably due to continued, normally rapid mesocortical DA synthesis for a period of time after the sudden blockade of impulse flow-coupled transmitter release 11,21.

DA neurones which lack nerve terminal autoreceptors show little (for example, the mesocortical system¹¹) or no (the tuberoinfundibular system²²) response to acute haloperidol challenge, while DA systems with terminal autoreceptors (for example, nigrostriatal, mesolimbic and tuberohypophyseal systems^{11,15,22}) respond dramatically. In the mesocortical system no tolerance to the effect of haloperidol challenge develops following chronic haloperidol administration, while tolerance does develop in the DA systems possessing nerve terminal autoreceptors⁶⁻¹⁰. Further, the time course for the development

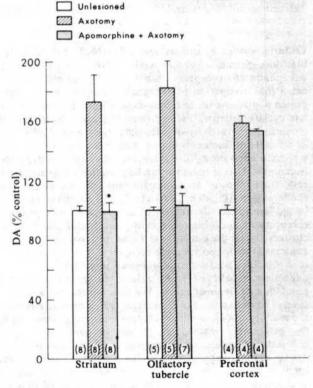

Fig. 3 Effects of apomorphine on nerve terminal DA autoreceptors after acute medial forebrain bundle axotomy. Lesions were made 35 min before decapitation using a retractable wire knife as described in the text. Some rats were pretreated with apomorphine (2 mg per kg, i.p.) 5 min before axotomy. The bars on the columns represent the s.e.m. and the numbers in the columns indicate n. DA levels in the unlesioned striata, olfactory tubercles and prefrontal cortices were $10,046 \pm 282, 4,948 \pm 115$ and 87 ± 3 ng per g respectively. * P < 0.001 when compared with animals receiving axotomies alone.

of tolerance in these systems may parallel the development of autoreceptor supersensitivity. These results suggest that the acute and chronic effects of haloperidol and other antipsychotic drugs on the various DA systems may be related to the presence or absence of nerve terminal autoreceptors. In addition, it has recently been determined that, in contrast to nigrostriatal and mesolimbic DA cells, mesocortical DA neurones innervating the prefrontal cortex also lack cell body DA autoreceptors (B. S. Bunney and L. A. Chiodo, personal communication).

The realization that mesocortical DA neurones lack both nerve terminal and cell body autoreceptors may aid in the development of potential therapeutic agents designed to interact selectively with discrete brain DA systems.

Opioid peptides induce reduction of enkephalin receptors in cultured neuroblastoma cells

Kwen-Jen Chang, Robert W. Eckel* & Steven G. Blanchard

Molecular Biology Department, Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709, USA Department of Neurology, University of North Carolina, Chapel Hill, North Carolina 27514, USA

Cultured mouse neuroblastoma cells (N4TG1)1,2 and neurocells (NG108-15)3-6 blastoma-glioma hybrid contain enkephalin (δ) receptors². Studies on hybrid cells have indicated that occupation of enkephalin receptors by opiates and opioid peptides leads to a time-dependent inhibition of adenylate cyclase activity3-5. If exposure of these cells to agonists is continued, the activity of adenylate cyclase gradually returns to normal and increases above normal on removal of opioids, a phenomenon thought to resemble tolerance and dependence in animals. Direct receptor binding studies on neuroblastoma cells have shown no internalization of receptors1. Using [D-Ala²,Lys⁶]Leu-enkephalin rhodamine-conjugated image-intensified fluorescence microscopy, enkephalin (δ) receptors in neuroblastoma cells were found slowly to form clusters which do not appear to be internalized. This is in contrast to many polypeptide receptors⁷⁻¹² which are internalized after the initial receptor-ligand interactions. This internalization is believed to be related to the so-called downregulation or desensitization. We now report that after one to several hours exposure of monolayer cell cultures to enkephalin, the number of enkephalin receptors measured subsequently in the extensively washed membrane preparations is greatly reduced. This reduction in receptor number seems to be selective for opioid peptides and is antagonized by a variety of opiate agonists and antagonists. These observations may be important in elucidating the phenomenon of opioid-induced desensitization.

Confluent monolayers of N4TG1 cells were pretreated with ligand, the cells were then washed extensively with Dulbecco's phosphate-buffered saline (PBS) to remove any remaining bound ligand and membrane particulate fractions were prepared. Enkephalin receptor binding of these fractions was then determined by measuring binding of ¹²⁵I-labelled [D-Ala²,D-Leu⁵]enkephalin (DADLE). Pretreatment of the cell monolayer for 4 h with 0.1 μM DADLE led to a large reduction in binding

of 125 I-DADLE to the subsequently prepared and washed membrane particulates. A similar loss of binding was observed for washed cells after pretreatment with DADLE; this reduction was time, temperature and dose dependent. At 37 °C, a significant reduction was observed after 30 min pretreatment, and had almost reached a maximum after 1 h. Further incubation only slightly increased the reduction (Fig. 1). Routinely we preincubated for 4h to ensure the maximum effect. At 24 °C, the reduction in binding was greatly decreased with respect to both the rate and extent of reduction (Fig. 1). The DADLE-induced reduction of binding is dose dependent (Fig.

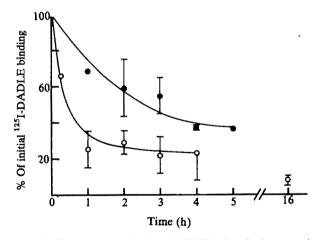

Fig. 1 Time course of the DADLE-induced decrease in ¹²⁵I-DADLE binding. N4TG1 cells were grown to confluence in Dulbecco's minimal essential medium supplemented with 75 U ml⁻¹ penicillin, 75 µg ml⁻¹ streptomycin sulphate and either 7% or 5% newborn calf serum (Gibco) in a 95% air/5% CO₂ humidified atmosphere at 37° C. DADLE was added to a final concentration of 10⁻⁷ M and the monolayers were incubated at 37 °C(O) or 24 °C (●) for the indicated times. After completion of the incubation, the medium was withdrawn, the monolayers were rinsed with PBS and the cells detached using 0.05% EDTA in PBS. The cells were pelleted by centrifugation, resuspended in PBS and incubated at 37 °C for 30 min to remove bound ligand. This incubation was repeated, then the cell pellet was resuspended in ice-cold 50 mM Tris pH 7.7 and the cells were homogenized using a Model PT-20 Polytron (setting 3.5, 20 s). The homogenates were centrifuged at 40,000g for 30 min and the resulting pellets were resuspended in 50 mM Tris pH 7.7 containing 100 mM NaCl; the suspensions were incubated at room temperature for 1 h. The membranes were again pelleted, resuspended and pelleted once in Tris buffer lacking sodium, and assayed for DADLE binding as previously described^{1,2}.

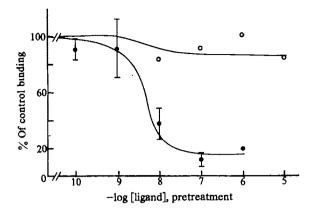

Fig. 2 Concentration dependence of the DADLE-induced decrease of enkephalin binding activity. Confluent monolayer cultures of N4TG1 cells were incubated with the indicated concentrations of DADLE (●) or morphine sulphate (○) for 4 h at 37 °C. Membrane fractions were prepared and binding activity was assayed as described in Fig. 1 legend. The data shown are the average values ±s.e.m. for two experiments.

2), having an EC₅₀ (concentration which causes 50% of the maximum reduction) of ~ 2 nM. This value is in reasonable agreement with the previously determined dissociation constant (K_d) of DADLE for the enkephalin receptor of this cell line^{1.2}.

The reduction in ¹²⁵I-DADLE binding activity induced by DADLE is specific for opiate receptors as this effect can be antagonized by the presence of an excess of opiate antagonists such as naloxone, nalorphine and diprenorphine (Table 1). These antagonists do not induce by themselves a reduction in ¹²⁵I-DADLE binding activity (Table 1). The natural endogenous peptides, Met- and Leu-enkephalin, as well as β -endorphin, [D-Ala²,NMePhe⁴,Met(O)ol⁵]enkephalin and [D-Ala²,Met⁵]enkephalinamide, also induce a reduction in ¹²⁵I-DADLE binding. Morphine and benzomorphan drugs such as ketocyclazocine and n-allylnormetazocine at high concentrations not only induce just a minimal reduction (usually ~20%) in the 125 I-DADLE binding activity (Table 1 and Fig. 2) but also antagonize the effect of opioid peptides (Table 1). This antagonistic effect of opiates against peptides is also dose dependent. Opiates are more effective against 0.01 µM DADLE than against a dose of 0.1 µM (Table 1), as would be predicted for competitive inhibition.

Incubation of cell monolayers with 10^{-8} M 3 H-DADLE at 37 °C for 4 h, followed by washing and preparation of membrane particulates in the same way as that used for the non-radioactive ligand, showed that 10% of the ligand initially associated with the cells remained bound. This corresponds to a concentration of DADLE $<10^{-10}$ M in the final assay. Because incubation of cells with 10^{-8} M DADLE caused a reduction of \sim 70% in the 125 I-DADLE binding (Fig. 2), the loss of binding activity could not be attributed simply to the competition of 125 I-DADLE with ligand that remained after preparation of the membrane fragments. Furthermore, diprenorphine, a ligand known to have an affinity greater than that of DADLE 13 , did not cause receptor reduction after similar pretreatment, suggesting that the peptide-induced receptor loss could not be explained simply by the high affinity of any ligand not washed away.

The enkephalin-induced reduction in binding is manifested by a decrease in the number of high-affinity binding sites, presumably enkephalin (δ) receptors. The saturation binding curves of ¹²⁵I-DADLE for control and 0.1 μ M DADLE-pretreated cell membranes showed a loss of total high-affinity binding sites (Fig. 3). The binding sites remaining after DADLE pretreatment had affinity similar to that of the control membranes. This was further confirmed by ¹²⁵I-DADLE competition binding studies using DADLE and morphine, in which we observed no significant difference in IC₅₀ values (concentrations

causing 50% inhibition of labelled binding) between control and pretreated membranes. As estimated from plots of log per cent ¹²⁵I-DADLE bound versus log concentration, the IC₅₀s for control and pretreated membranes respectively were 1.5 and 1.0 nm when DADLE was the displacing ligand and 35 and 75 nM for morphine sulphate, in good agreement with previous reports^{1,2,14}. However, it is unknown whether this reduction in the number of high-affinity binding sites is due to a loss of receptor sites or whether they are converted to sites of low affinity not detected in our binding assay. Recently, Bowen et al. ¹⁵ have reported an interconversion of μ and δ receptors in rat striatal patches that is mediated by divalent cations and sulphydryl reagents. Because pretreatment of N4TG1 cells with DADLE results in a loss of ³H-diprenorphine binding (a compound having similar affinity for μ and δ receptors) as well as ¹²⁵I-DADLE binding (data not shown), it seems unlikely that conversion from a δ to a μ form of receptor resulted in the observed down-regulation effect.

Numerous experiments in vivo and in vitro have indicated that enkephalin can mimic the biological effects of morphine, including the development of tolerance and physical dependence¹⁶. Previous experiments in vivo have led to the conclusion that neither the number nor the affinity of opiate receptors are altered after chronic treatment with morphine 17-20. We have confirmed this from measurements of the binding activities of three subtypes of opiate receptors including morphine (μ) , enkephalin (δ) and benzomorphan binding sites²¹ after chronic morphine treatment. Thus, the effect of reducing receptor numbers may be selective for opioid peptides and may differ from the phenomena of in vivo morphine tolerance and dependence. However, the recent demonstration of the lack of cross-tolerance between a δ -agonist (DADLE) and a μ -agonist (sulphentanyl) in mouse vas deferens after chronic in vivo treatment with either ligand²² suggests that there may exist tolerance selective for a receptor subtype. N4TG1 cells contain δ -receptors only. The present studies demonstrate that only opioid peptides induce a decrease in enkephalin receptors; morphine (μ -agonist), ketocyclazocine (κ -agonist) and N-allylnormetazocine (σ -agonist) have no such effect, in fact they antagonize the effects of opioid peptides. These observations resemble the studies on mouse vas deferens²². Selective

Table 1 Specificity of the ligand-induced decrease in enkephalin receptors

All ligands were preincubated with cells for 4 h before collection of the cells and preparation of membranes. As determined by Student's *t*-test, all values for peptides and morphine at 5×10^{-5} M differ significantly from the control (100%) (P < 0.005); all values for oplate agonists and antagonists except morphine at 5×10^{-5} M do not differ significantly from the control (P > 0.1). The values for oplates plus DADLE, except morphine (10^{-5} M) plus DADLE (10^{-7} M), differ aignificantly from the values for DADLE alone (P < 0.005)

*[DADLE] = 10^{-7} M

^{†[}DADLE] = 10⁻⁸ M

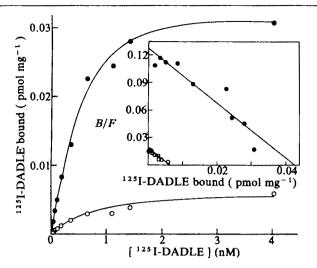

Fig. 3 Binding of 125 I-DADLE to N4TG1 membranes before and after preincubation of cells with unlabelled DADLE. Confluent cultures of N4TG1 cells were incubated with (O) or without (1) 10⁻⁸ M unlabelled DADLE and membranes were prepared as described in Fig. 1 legend Aliquots of the membranes were incubated with various concentrations of ¹²⁵I-DADLE for 1 h, after which time bound ligand was determined by rapid filtration through glass fibre filters. Nonspecific binding was determined in the presence of 10⁻⁵ M unlabelled DADLE. Inset, Scatchard plot of the data. The control membranes had a K_d of 0.76 nM and B_{max} of 42.8 fmol mg⁻¹, while the respective values for the treated membranes were 0.83 nM and 6.4 fmol mg⁻¹.

desensitization due to the loss of opiate receptors could occur for δ -receptors after chronic opioid peptide treatment.

There are many possible mechanisms for the ligand-induced loss of receptors reported here. For example, desensitized lowaffinity receptors may be induced by peptide which can no longer be detected by the present binding method. It is also possible that the receptors are cryptic after treatment with opioid peptides. The formation of (essentially) irreversible receptor-ligand complexes may also occur during the pretreatment. An understanding of the mechanism of receptor reduction may prove important in elucidating the physiological and pathological actions of opioids.

We thank Dr Pedro Cuatrecasas for reviewing the manuscript and for helpful discussion, and Mr Mark Collins for technical assistance.

Related amino acid sequences in neurofilaments and non-neuronal intermediate filaments

Norhert Geisler, Uwe Plessmann & Klaus Weber

Max-Planck Institute for Biophysical Chemistry, D-3400 Göttingen, FRG

The major constituents of mammalian neurofilaments are the three triplet proteins of molecular weight 200,000 (200K), 145K and 68K, which also co-migrate in slow axonal transport¹⁻⁵. Partial amino acid sequence data⁶ and chemical cleavage patterns^{7,8} indicate that various cell-specific nonneuronal intermediate filament proteins having molecular weights between 40,000 and 70,000 are structurally related, consistent with a common filament morphology. Here we extend this principle to the neurofilament 68K triplet protein, NF68. We show that NF68, muscle-specific desmin (52K) and mesenchymally derived vimentin (55K) are related proteins. Direct amino acid sequence analysis of a uniquely positioned marker peptide (5K) shows that in this region, NF68 shows ~42% sequence identity with vimentin and desmin, which have ~70% identity. These results are discussed with respect to neurofilament organization.

Treatment of porcine vimentin (55K) and desmin (52K) with the cysteine-specific reagent 2-nitro-5-thiocyanobenzoic acid (NTCB)⁹ yields two fragments (I and II)⁶. Whereas fragments I (37K) spanning the amino-terminal part of the two polypeptides were not further explored, the two carboxy-terminal fragments II (15K) were fully characterized and revealed 64% amino acid sequence identity between vimentin and desmin⁶. Similar treatment of NF68 isolated from porcine spinal cord¹⁰ gave rise to two fragments of 37K (I) and 28K (II) (Fig. 1). End-group analysis localized fragment II to the carboxyterminus (Fig. 2). For direct sequence comparison, we examined cleavage at another amino acid residue, which is rare in intermediate filament proteins^{6-8,11,12}. BNPS-skatole, assumed to

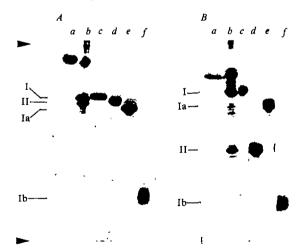

Fig. 1 SDS-polyacrylamide gel electrophoresis of vimentin, desmin and NF68 and their fragments. A and B show NF68 and vimentin, respectively; desmin behaved similarly to vimentin. Porcine proteins (a) were isolated as described elsewhere $^{10-12}$ and cleaved at cysteine $^{6.9}$ to yield fragments I and II (b; see also Fig. 2). The two fragments were isolated by preparative gel electrophoresis⁶ (c and d) and fragments I (c) were further cleaved with BNPS-skatole¹³ to yield two fragments Ia and Ib, which were isolated by preparative gel electrophoresis (e, f). The purified Ib fragments (f) were freed of SDS and processed for protein sequencing as described elsewhere 6.12,26. Alternatively, peptides resulting from cysteine cleavage were mixed and subjected to tryptophan cleavage. Again Ib fragments were isolated from 20% polyacrylamide gels. For localization of fragments see Fig. 2.

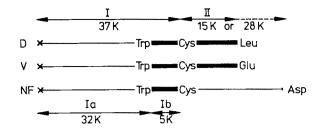

Fig. 2 Organization of the polypeptide chains of porcine desmin (D), vimentin (V) and the neurofilament 68K protein (NF). The relative positions of fragments I and II, obtained by cysteine cleavage of desmin and vimentin, have been given elsewhere⁶. In both cases fragments Ib obtained by tryptophan cleavage occupy the carboxy-terminal part of fragment I, as it has the same carboxyterminal residue (0.8 mol threonine per mol polypeptide by carboxypeptidase Y digestion), whereas fragments Ia contain the blocked (X) amino-terminal end. NF68 fragment II must occupy the carboxy-terminus, as it has the same carboxy-terminal endgroup as NF68 (0.5 mol aspartic acid per mol polypeptide determined by hadrazinolysis), whereas fragment I contains the aminoterminal blocking group and a new carboxy-terminal end (0.3 mol alanine per mol determined by hydrazinolysis). Fragment Ib is assigned again by the end-group results of fragments I, Ia and Ib. Amino-terminal fragments I have approximately the same molecular weights (see Fig. 1), whereas the carboxy-terminal fragments II differ between NF68 and the two other proteins and account for the marked molecular weight differences between NF68 (68K) and vimentin or desmin (55-52K). (For a comparison of the sequences of fragment II from desmin and vimentin, see ref. 6.) Portions of the polypeptides which have been sequenced are indicated by solid boxes.

cleave preferentially at tryptophan¹³, gave a fragmentation pattern indicating a single tryptophan residue situated ~40 residues amino-terminal from the sole cysteine residue documented previously⁶ (Figs 1, 2). Thus double chemical cleavage, first with NTCB and then with BNPS-skatole, provided two new fragments for all three proteins: a large amino-terminal fragment Ia (32K) and a small fragment Ib (5K) in addition to fragment II. Figure 2 indicates that the increased molecular weight of NF68 compared with desmin and vimentin (52-55K) may be accounted for by a larger carboxy-terminal fragment II, the sequence of which has not yet been determined.

The small size of fragments Ib allowed an assessment of the sequence homology suggested by the similar relative localization of tryptophan and cysteine residues in the three distinct proteins (Figs 2, 3). Although of different length (37 and 42 residues), the three fragments are related (Fig. 3). In the case of the vimentin and desmin sequences, 28 out of 39 residues

N Ile - Glu - Ala - Cys

(72%) are identical; this per cent identity is comparable to that found previously for the 140 residues of the corresponding fragments II (64%)⁶. In the case of NF68 fragment Ib, the sequence homology is clearly lower, both in comparison with vimentin (43%) and with desmin (41%) fragments Ib. Thus the similarity in the relative location of cysteine and tryptophan in NF68 compared with vimentin and desmin (Fig. 2) is supported by a similarity in sequence of the resulting fragments Ib (Fig. 3). Although there is a small insertion in this NF68 fragment, many of the other amino acid exchanges are conservative. These results support the hypothesis that neuronal and non-neuronal intermediate filament proteins are related in sequence and belong to a multi-gene family, which is expressed according to certain rules of embryonic differentiation, and which largely coincide with histologically distinct cell types 14-17.

Present models of intermediate filament structure developed for epidermal keratins⁷ and extended to vimentin and desmin⁸ assume a similar 3-polypeptide unit, which contains regions of coiled-coil α -helix interspersed with regions of non- α -helix. Two long α -helices are thought to be present in the aminoterminal two-thirds of the molecules. As it is reasonable to assume that such α -helices have conserved sequences^{7,8} and because our sequence data so far cover only that part of the molecule assumed to be non-helical, more extensive protein data may reveal a higher degree of sequence similarity between different intermediate filament proteins than is presently indicated (our results and ref. 6). Note, however, that in the case of NF68, chain length variation seems to be achieved by an alteration, insertion or addition in the carboxy-terminal domain (Figs 1, 2), whereas previous studies on epidermal keratins indicated that the region between the two helical domains is the major determinant of variant molecular size8.

The sequence homology observed between NF68 and two distinct non-neuronal intermediate filament proteins agrees with our finding that purified 68K protein alone can self-assemble in vitro to form smooth 10-nm filaments¹⁰. What then is the function of the two higher molecular weight neurofilament triplet proteins? They may either act as associated proteins binding to a filament backbone provided solely by the 68K protein, as indicated by antibody decoration studies for the 200K protein present in native neurofilaments^{4,18}, or may themselves form part of the filament backbone. The latter possibility is suggested but not proved by several observations. Although the three triplet proteins possess unique and distinct antigenic determinants^{4,19}, several studies suggest the presence of common determinants^{2,4,17,19-21} defined by a recently characterized hybridoma antibody, which not only recognizes the three triplet proteins but also at least several distinct non-neuronal

Fig. 3 Comparison of the amino acid sequences of the marker peptide Ib (see Figs 1, 2) from porcine desmin (D), vimentin (V) and neurofilament NF68 protein (N). Identical residues in desmin and vimentin are indicated by lines over the desmin sequence. Identical residues in vimentin and NF68K protein are underlined in the NF68 sequence. Note the high degree of homology between desmin and vimentin and the lower homology between these proteins and the NF68 polypeptide. The first (Trp) and last (Cys) residues are not present in the isolated fragments but represent the overlapping residues to fragments Ia and II, respectively (see Fig. 2). They are included in the sequences for better alignment and emphasize the small insertion in the carboxy-terminal region of the NF68 fragment Ib

intermediate filament proteins²². If these results indicate common functional amino acid sequences, the two higher molecular weight triplet proteins may be incorporated at least in part into the filament backbone. This possibility is also suggested by their relative abundance compared with the 68K protein^{1-5,10,17-21,23}, which makes it difficult to envision them solely as associated proteins in the sense of microtubule-associated proteins present in microtubules²⁴. In addition, in the invertebrate Myxicola, neurofilaments have no NF68 and consist of only two polypeptides²⁵ having molecular weights of 150K and 160K, and which are antigenically related to mammalian intermediate filament proteins 17,22. Clearly more chemical and structural information is needed to elucidate neurofilament architecture.

We thank S. Lechte for technical assistance and Dr G. Shaw or discussions. This work was supported by the Max-Planck Society and a grant from the Deutsche Forschungsgemeinschaft (We 338/2).

Note added in proof: We have recently found that bovine glial fibrillary acidic protein (GFA) shows the same distribution of tryptophan and cysteine residues as given in Fig. 2 for desmin and vimentin.

Influence of ionic current on Na+ channel gating in crayfish giant axon

Peter Shrager & Mei-Ven C. Lo

Department of Physiology, University of Rochester Medical Center, Rochester, New York 14642, USA

In studies of nerve excitation it is important to examine the possible interaction of voltage-sensitive gating mechanisms with components forming the pathway of ionic channels. There is evidence that permeant ions and gating are independent in Na channels^{1,2} of nerve fibres, but not in K⁺ channels³. Of interest in this and other studies of excitability is the determination of the physical basis for the resistance in series with the axon membrane $(R_i)^4$. In an attempt to determine whether an appreciable R, is associated with individual Na⁺ channels⁵, we have compared gating kinetics in conditions in which the ionic current through individual channels is varied while the total membrane current remains constant. The number of conducting Na^+ channels, and thus their contribution to R_* , was lowered by addition of tetrodotoxin6. We report here that no more than 10% of the resistance in 'series' with activation gates is associated with the Na+ channel, and give some preliminary estimates for minimum distances between gates and ion-binding sites within the Na+ channel.

The most common method of measuring R_{\bullet} uses the response to a hyperpolarizing step in current-clamp, a condition in which most Na⁺ channels are closed. The influence of R_* is seen most clearly, however, in a dependence of Na+ channel gating kinetics on the magnitude of Na⁺ currents. As we wished to make no assumptions regarding the identity of these two resistances, our experiments used very small ionic currents and no electronic compensation for R_* . Crayfish giant axons were voltage-clamped and internally perfused^{7,8}. Two external solutions were required: 100% Na contained (mM) Na⁺, 210.2; K⁺, 1; Mg²⁺, 2.6; Ca²⁺, 13.5; Cl⁻, 293.3; HCO₃, 2.3; HEPES, 2.5; 4-aminopyridine, 2, $pH7.70\pm0.05$ at 8°C; 6 % Na was identical except that all but 13.8 mM of Na⁺ was replaced by tetramethylammonium ion. The difference in liquid junction potential at the reference electrode on switching between these solutions was <1 mV and has been ignored. Measurements were made on the kinetics of closing of activation and inactivation gates, first in 6 % Na, then in 100 % Na-3.2 nM tetrodotoxin (TTX). Pulse protocols were then repeated in each solution with 100 nM TTX. Conditions were thus set so that closing kinetics could be measured either with many channels open, but low ionic current per channel, or with few channels open but high current per channel. The experiments were designed to keep total ionic current small and equal in the two cases. After several preliminary experiments to establish the best procedures, the following data were obtained from five axons.

Families of Na⁺ currents used in the determination of inactivation time constants (τ_h) are shown in Fig. 1; τ_h is a measure of the rate of decay of Na+ currents under a maintained depolarization. 100 % Na+3.2 nM TTX provided a good match of peak currents with those in 6 % Na, particularly at lower depolarizations, which were of primary interest. Figure 2 plots τ_h against V_m ; relatively little variation is seen among the different fibres in each solution. The shift in the points from 6 % Na (open symbols) to 100 % Na + 3.2 nM TTX (solid symbols), measured in the region of greatest slope (-20 to -40 mV),

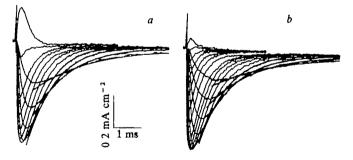

Fig. 1 Families of Na⁺ currents. a, 6% Na; b, 100% Na+3.2 nN TTX. Three consecutive sweeps were averaged by the computer in all cases. K⁺ currents were reduced by 4-aminopyridine^{15,16} and eliminated by subtraction of records in 100 nM TTX. Pulses at low depolarizations were of longer duration than shown to allow an accurate determination of exponential fits to Na+ current decay. Pulses at high depolarizations were of short duration. Fits of single exponentials to inactivation were made using strict and consistent criteria: there was no adjustment of the baseline and the fit was made between 10 and 70% of the peak current. Fits at the four lowest depolarizations are shown superimposed. It has been previously demonstrated 14,17 that inactivation kinetics in the crayfish axon are well described by a single time constant. Holding potential, -76 mV; 50 ms prepulses to -116 mV and a 0.5 ms return to -76 mV preceded depolarizations to a (6 % Na): --31, -26, -21, -16, -11, -6, -1, +4, +14, and +24 mV. In 100 % Na+3.2 nM TTX (b), additional depolarizations to +34, +44, +54, +64 and +74 mV are shown. External solutions are described in the text. The internal perfusate contained (mM) K 230, Na⁺, 5; F⁻, 119; Cl⁻, 5; citrate ion, 37; mannitol, 93; pH 7.35.

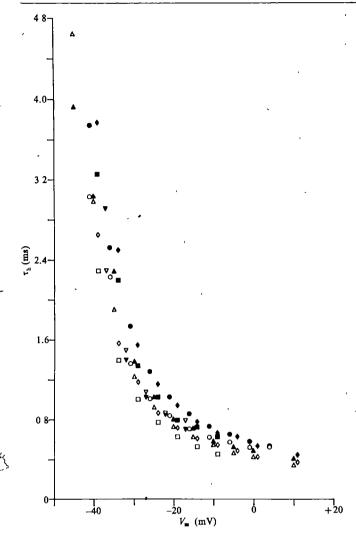

Fig. 2 Inactivation time constants plotted against membrane potential. Data from five axons. Open symbols, 6 % Na; solid symbols, 100 % Na+3.2 nM TTX. Single exponentials were fitted to Na⁺ current decays using a weighted least-squares procedure.

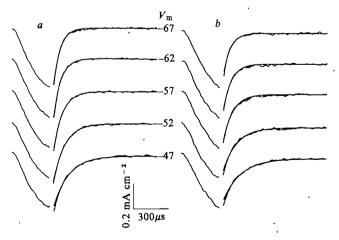

Fig. 3 Na⁺ tail currents. a, 6 % Na; b, 100 % Na+3.2 nM TTX. Three consecutive sweeps were averaged. Holding potential, $-77 \,\mathrm{mV}$. A hyperpolarizing prepulse to $-117 \,\mathrm{mV}$ removed resting inactivation. The fibre was depolarized to $-22 \,\mathrm{mV}$ for 0.4 ms and V_{m} was then changed to the values shown. Records of ionic current are shown after subtraction of traces in 100 nM TTX. Exponential fits are superimposed on tail currents and are generally adequate. At the highest depolarizations used (\sim -45 mV), a second small (<10%) and very slow component ($\tau \simeq \tau_{\mathrm{h}}$) was sometimes seen and was subtracted before fitting. Only 4 of the 44 points used in calculating shifts in Fig. 4 required this procedure.

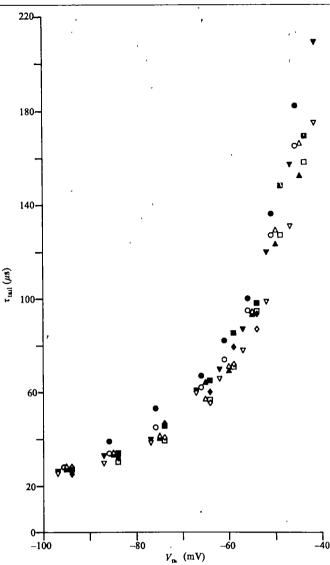

Fig. 4 Na⁺ tail current time constants plotted against membrane potential. Points are from the same axons as in Fig. 2. Open symbols, 6 % Na; solid symbols, 100 % Na+3.2 nM TTX.

is $+3.1\pm1.0\,\mathrm{mV}$ (\pm s.e.m.). This shift is small and is in the opposite direction to that expected for a series resistance. For inward currents, the $R_{\rm e}$ voltage drop causes measured $V_{\rm m}$ values to be more negative than actual membrane potentials.

An example of Na⁺ tail currents is given in Fig. 3. In contrast to $\tau_{\rm h}$, $\tau_{\rm tail}$ measures the rate of decay of Na⁺ conductance when a depolarization is abruptly interrupted and $V_{\rm m}$ returned to a more negative value⁹. Fits to single exponentials are superimposed and are seen to be generally satisfactory. Figure 4 shows $\tau_{\rm tail}$ plotted against $V_{\rm m}$. The shift along the voltage axis from 6 % Na (open symbols) to 100 % Na+3.2 nM TTX (solid symbols), measured between -70 and -45 mV, is -2.0±0.4 mV. This is again small, but this time is consistent with a channel-associated $R_{\rm s}$.

Current-clamp techniques give a total R_{\bullet} of 4–6 Ω -cm² in crayfish axons⁷. Furthermore, with no R_{\bullet} compensation, voltage shifts in τ_h - V_m curves on changing from 100 % Na (no TTX) to 6 % Na, divided by the difference in current amplitude, suggest an R_{\bullet} of 6–7 Ω -cm². We shall use 6 Ω -cm² as a reasonable value in order to estimate the magnitude of some possible sources of error. At midpoints of the voltage ranges used to determine shifts (-30 mV for τ_h and -58 mV for τ_{tail}), average maximum currents were 0.38 mA cm⁻² (τ_{tail}), suggesting that errors due to uncompensated Schwann cell R_{\bullet} should be at most ~2.4 mV. This is confirmed by the observation that despite the significant ranges of maximum currents in different axons in the same solution (for example,

 $0.2-0.5 \text{ mA cm}^{-2} \text{ used } \cdot \text{to measure } \tau_h \text{ in } 6 \% \text{ Na}; 0.3 0.6~\mathrm{mA~cm^{-2}}$ in the case of τ_{tail} in 6 % Na), the time constants vary over only a 2-mV span at these potentials. Our experiments have been designed to reduce such errors further by keeping current magnitudes equal in the two external solutions. The mean difference (value in 6 % Na minus that in 100 % Na+ 3.2 nM TTX) was 0.06 mA cm^{-2} for measuring τ_h and 0.20 mA cm^{-2} for τ_{tail} . $R_s \Delta I$ then represents a small correction so that the shifts along the voltage axis in changing from 6 % Na to 100 % Na + 3.2 nM TTX become +2.7 \pm 1.0 mV for τ_h and -3.2 ± 0.4 mV for $\tau_{\rm tail}$.

We calculate that in the five axons analysed for shifts, the difference in peak Na⁺ currents between 100 % Na (no TTX) and 6 % Na was ~5 mA cm⁻². Since the Na⁺ current per channel should be unchanged by the addition of 3.2 nM TTX¹⁰, the shift in gating kinetics expected if all the R. were associated with individual Na+ channels is -30 mV. Our results suggest that with regard to activation, almost 90% of the R_{\star} is not of this form and is probably a reflection of the Schwann cell connective tissue sheath. Furthermore the small residual resistance shows no systematic voltage dependence in the range of $V_{\rm m}$ in which activation is highly voltage-dependent. Mathias et

al.5 have postulated that a channel-associated, voltage-dependent R_1 might account for gating charge movement; our results suggest that this is inappropriate for nerve Na⁺ channels. Salzberg et al.11, using an optical probe, measured the Schwann cell contribution to R_{\bullet} in squid axons as 2.8 Ω -cm².

The shifts that were measured in our experiments are small and are in opposite directions. One possible explanation might reside in an electrostatic interaction in which a Na+ ion bound at a site within the channel 12,13 stabilizes the voltage-sensitive components of gates in their open states¹⁴. Because of the opposite voltage dependence of $au_{\rm h}$ and $au_{\rm tail}$ in the $V_{\rm m}$ ranges considered, a slowing of each time constant would result in shifts of opposite sign. From the K_d of 368 mM measured by Hille¹², and the Na⁺ concentration in 100 % Na, at least one site in the channel might be occupied for about one-third of the time the channel is open. Then, for a shift of 3 mV, and assuming a uniform dielectric with no intervening counterions, we calculate the minimum distance between Na+ ion and gate voltage sensor to be 20 Å. If the effective dielectric constant is less than 81, this value would be proportionally higher.

Nerve impulses increase the phosphorylation state of protein I in rabbit superior cervical ganglion

Eric J. Nestler & Paul Greengard

Department of Pharmacology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA

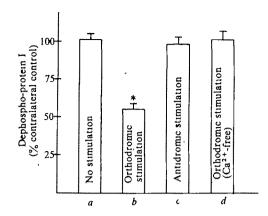

Protein I, a neurone-specific protein concentrated at synapses, is present in most, and probably all, presynaptic nerve terminals where it is at least partially associated with neurotransmitter vesicles (refs 1-5 and P. De Camilli, W. B. Huttner, R. Cameron, M. Harris and P.G., in preparation). Protein I is a major endogenous substrate in nervous tissue for both cyclic AMP-dependent and calcium/calmodulin-dependent protein kinases. Neurotransmitters^{9,10}, apparently acting through cyclic AMP, and depolarizing agents9-11, apparently acting through calcium, have been shown to increase the state of phosphorylation of protein I in intact preparations of the central and peripheral nervous systems. To determine whether impulse conduction regulates the state of phosphorylation of protein I, we have now studied this process in the rabbit superior cervical ganglion, a well characterized neuronal preparation that is suitable for both physiological and biochemical studies. Using a technique developed to quantify the state of phosphorylation of the small amounts of protein I contained in ganglion tissue, we show here that in physiological conditions brief periods of impulse conduction increase the state of phosphorylation of protein I in this ganglion.

New Zealand White rabbits (1.5-2.5 kg) were used in this study. The two superior cervical ganglia of each rabbit contained almost identical amounts of dephospho-protein I when neither ganglion was stimulated (Fig. 1a). Therefore, one ganglion from each rabbit served as the 'test' ganglion and the contralateral ganglion as the control. When the preganglionic nerves supplying the test ganglia were stimulated at 10 Hz for 30 s (a frequency of impulse conduction observed in vivo 12), there was a decrease in the amount of dephospho-protein I compared with that in the contralateral control ganglion (Fig. 1b). As the

total amount of protein I, determined by radioimmunoassay, was not altered by nerve stimulation (data not shown), the results demonstrate that in physiological conditions impulse conduction increased the state of phosphorylation of protein I in the rabbit superior cervical ganglion. In contrast to stimulation of preganglionic nerves (orthodromic impulse conduction), stimulation of postganglionic nerves (antidromic impulse conduction) at 10 Hz for 30 s did not alter protein I phosphorylation (Fig. 1c). Furthermore, the effect of preganglionic nerve stimulation on protein I phosphorylation was dependent on extracellular calcium (compare Fig. 1b with d).

Tables 1 and 2 show the state of phosphorylation of protein I in the rabbit superior cervical ganglion as a function of the number of impulses conducted along the preganglionic nerve. In one series of experiments (Table 1a), the preganglionic nerves supplying test ganglia were stimulated at 10 Hz for various periods of time and the amount of dephospho-protein I present immediately after the period of nerve stimulation was determined. An increase in protein I phosphorylation was first observed after 10 s of nerve stimulation (100 impulses) and appeared to be maximal after 20 s (200 impulses). In a related series of experiments (Table 1b), the preganglionic nerves supplying test ganglia were stimulated at 10 Hz for various periods of time as in Table 1a, and the amount of dephosphoprotein I present 30 s after the initiation of nerve stimulation was determined. In these conditions, 2 s of nerve stimulation (20 impulses) significantly increased protein I phosphorylation and 5 s of nerve stimulation (50 impulses) appeared to produce a maximum in protein I phosphorylation.

In further experiments (Table 2), the preganglionic nerves supplying test ganglia were stimulated for 5 s at various frequencies and the amount of dephospho-protein I present 30 s after the initiation of nerve stimulation was determined. The state of phosphorylation of protein I was increased when ganglia were stimulated at 5 Hz (25 impulses) and 10 Hz (50 impulses), but not at lower frequencies. Figure 2 shows the change in dephospho-protein I observed in response to 5 s of preganglionic nerve stimulation at 10 Hz as a function of the time after initiation of nerve stimulation. An increase in the state of phosphorylation of protein I was first observed 20 s after initiation of nerve stimulation and appeared to be maximal at Fig. 1 Regulation by impulse conduction of the state of phosphorylation of protein I in the rabbit superior cervical ganglion. Rabbits were injected intravenously with 1 ml (50 mg) sodium pentobarbital (Nembutal, Abbott) and then were killed by air embolism. The two superior cervical ganglia of each rabbit, with their pre- and postganglionic nerves, were quickly dissected, placed in a chamber and superfused at room temperature with oxygenated Locke's buffer (mM). 136 NaCl; 5.6 KCl; 20 NaHCO₃, 1 2 NaH₂PO₄; 2 2 CaCl₂, 1 2 MgCl₂, 0.18% glucose (pH 7.4) The ganglia were carefully decapsulated and then superfused for 30-45 min with a-c, standard Locke's buffer; d, calcium-free Locke's buffer (2.2 mM MgCl₂ and 1 mM EGTA were substituted for 2.2 mM CaCl₂) One ganglion from each rabbit served as the 'test' ganglion, and the other as the control a, Test ganglia were mounted in suction electrodes, but not stimulated b, d, The preganglionic nerve supplying the test ganglion was stimulated via a suction electrode with supramaximal pulses at 10 Hz for 30 s. The effectiveness of stimulation was monitored by recording compound action potentials from postganglionic nerves using a second suction electrode c, The postganglionic nerves supplying the test ganglion were stimulated at 10 Hz for 30 s using a suction electrode. Immediately after the 30 s period of nerve stimulation, test and contralateral control ganglia were homogenized in 400 µl of 1% SDS using conical glass tissue homogenizers (Belco). The SDS homogenates were boiled for 5 min and then centrifuged for 2 min in a Beckman microfuge. The supernatants ('SDS extracts') contained essentially all the total protein I as determined by radioimmunolabelling of gels. SDS extracts were used to quantify the amount of dephospho-protein I and the total amount of protein I. The former was assayed by a 'back phosphorylation' technique in which the

protein I in SDS extracts was first immunoprecipitated and then phosphorylated with purified protein kinase. The immunoprecipitation reaction was carried out at 0.4°C in plastic microfuge tubes. Duplicate aliquots (60 µl) of the SDS extract from each ganglion were adjusted by addition of a 200 µl solution to contain (mM; final concentrations) 250 NaC; 50 NaF; 14 EDTA; 10 sodium phosphate, pH 7.4, 15% (v/v) Nonidet P-40. To these were added 4 µl of the γglobulin fraction of anti-protein I rabbit antiserum. The mixture was incubated for 20 min, then 3 µg of purified rabbit IgG (Sigma) and 20 µl of the IgG fraction of goat anti-rabbit IgG (Sigma, 1 ml of goat IgG precipitated 2-3 mg of rabbit IgG) were added. After incubation for 3 h, the mixture was centrifuged in a microfuge for 1 min. The pellet was washed with 200 µl ice-cold 150 mM NaCl/10 mM sodium phosphate, pH 7.4, and then dissolved in 50 µl of ice-cold 11 mM citric acid (final pH ~3). The dissolved pellet was phosphorylated as described elsewhere¹⁰, with the following modifications. The assay mixture (final volume, 70 µl) contained 50 mM HEPES, pH 7.4; 10 mM MgCl₂, 0 1 µM purified catalytic subunit (beef heart cyclic AMP-dependent protein kinase, provided by A. C. Nairn); 15 mM dithiothreitol, 0 005% Nomdet P-40. The phosphorylation reaction was initiated by adding 30 µl [γ-³²P]ATP (final concentration 2-3 µM, specific activity 0 5-1×108° c p.m. nmol⁻¹), and was carried out at 30 °C for 30 min. The reaction was terminated by boiling the mixture in 'SDS-stop solution' as described elsewhere¹⁰ The boiled phosphorylated extract was then subjected to SDS-polyacrylamide gel electrophorories as described previously¹⁰, except that the lower (resolving) gel contained 9% acrylamide with a ratio of acrylamide to methylenebisacrylamide gel electrophorories and described previously¹⁰, except that the lower (resolving) gel contained 9% acrylamide with a ratio of acrylamide to methylenebisacrylamide gel electrophorories as described previously¹⁰, excep

Table 1 Effect of number of impulses of constant frequency (10 Hz) on protein I phosphorylation

а	No. of impulses	Duration of nerve stimulation (s)	Dephospho-protein I immediately after nerve stimulation (% contralateral control)	b	No. of impulses	Duration of nerve stimulation (s)	Dephospho-protein I 30 s after initiation of nerve stimulation (% contralateral control)
	0	0	$102 \pm 4 (6)$		0	0	102 ± 4 (6)

30-60 s, after which the state of phosphorylation of protein I returned to control levels.

Related studies (E.J.N. and P.G., in preparation) on the rabbit superior cervical ganglion have indicated that the ganglion contains two 'pools' of protein I. One pool, representing ~60% of total ganglion protein I and which is located in presynaptic nerve terminals, disappears on surgical denervation of the ganglion but is unaffected by brief exposure to the protein synthesis inhibitor, cycloheximide. The other pool, representing ~40% of total ganglion protein I, is located in the cell bodies of the ganglionic neurones. This postsynaptic pool is unaffected by denervation but is decreased by brief exposure to cycloheximide. Thus, postsynaptic protein I appears to represent newly synthesized protein I, presumably en route to the nerve terminals arising from the ganglionic cell bodies.

The state of phosphorylation of protein I is increased not only by impulse conduction, but also by dopamine and by high K^+ in intact rabbit superior cervical ganglia (E.J.N. and P.G., in preparation). In contrast, dopamine and high K^+ did not alter protein I phosphorylation in denervated ganglia. Furthermore, the effect of impulse conduction on the state of

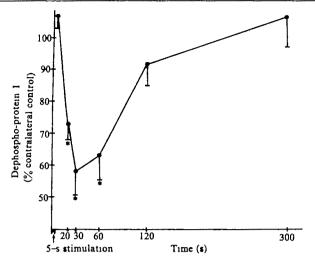

Fig. 2 Effect of a brief period (5 s) of impulse conduction on amount of dephospho-protein I, as a function of time after stimulation. The preganglionic nerve supplying one ganglion of each rabbit was stimulated via a suction electrode at 10 Hz for 5 s; stimulated and contralateral control ganglia were homogenized in 1% SDS at various times afterwards. Dephospho-protein I was determined as described in Fig. 1 legend, and the amount in the stimulated ganglion compared with that in the contralateral control ganglion. Values shown are mean ± s.e.m. The number of pairs of ganglia used ranged from 3 to 7. * Significantly different from control (P < 0.05) by two-tailed t-test.

phosphorylation of protein I was not blocked by those neurotransmitter antagonists that abolish the three postsynaptic potentials observed in the ganglion. These results suggest that the state of phosphorylation of presynaptic protein I, but not that of postsynaptic protein I, is regulated by impulse conduction, by dopamine, and by high K⁺

We have shown that brief periods of impulse conduction at physiological frequencies¹² increase the state of phosphorylation of protein I in the rabbit superior cervical ganglion. This effect is dependent on extracellular calcium, suggesting that impulse conduction increases protein I phosphorylation through the activation of calcium-dependent protein kinase(s)8. We have also found that dopamine and 8-bromo-cyclic AMP increase the state of phosphorylation of protein I in rabbit ganglia, in the presence or absence of extracellular calcium (E.J.N. and P.G., in preparation), suggesting that these agents increase protein I phosphorylation through the activation of cyclic AMPdependent protein kinase1. It is interesting to note in this context that cyclic AMP^{13,14} and calcium^{15,16} have also been shown to modulate neurotransmitter release at various synapses. Catecholamines including dopamine, apparently acting through cyclic AMP¹⁷, and brief periods of impulse conduction, apparently acting through calcium^{18,19}, produce long-lasting facilitation of neurotransmitter release in vertebrate sympathetic ganglia. It is possible that an increase in the state of phosphorylation of protein I may be one of the mechanisms by which certain neurotransmitters and brief periods of impulse conduction facilitate neurotransmitter release.

Class I loci of the human major histocompatibility complex (MHC) encode 44,000-molecular weight polypeptides that associate nonconvalently with β -microglobulin¹. Included in this category are the HLA-A, -B and $-\bar{C}$ loci (Fig. 1a), which are extensively polymorphic². HLA-specific cDNA clones³. now allow this polymorphism to be studied at the DNA level. However, the lack of sufficient amino acid sequence data for all but a few of the class 1 antigens presents a major difficulty in the allelic assignment of those DNA clones obtained in man³ and mouse⁶⁻⁸. HLA loss variants produced with deletioninducing ionizing radiation offer a means of partially circumventing the time-consuming and difficult task of sequencing HLA class I gene products for identifying restriction enzyme digest fragments of DNA and recombinant DNA clones. P.K. et al.9 used y-ray irradiation followed by immunoselection to obtain many mutants that no longer expressed one or more HLA specificities from the human lymphoblastoid cell line LCL 721. Only the expression of HLA-B8 was lost in one class of mutant, while expressions of HLA-B8 and at least one additional cis-linked HLA allele were lost in mutants of the second class. Some mutants lost expression of the entire haplotype, that is, HLA-A1, -B8 and -DR3 (ref. 9) as well as SB (refs 4, 10 and unpublished results). Recently, anti-HLA-B5 and anti-HLA-A2 sera have been used to isolate mutants that have lost expressions of one or more loci of the haplotype on the other chromosome 6 of LCL 721 (Table 1)10. Data presented here illustrate how one cDNA clone of an HLA class I gene, pHLA-1, in combination with γ -ray-induced HLA loss variants, will be used to identify recombinant DNA HLA clones and to correlate individual DNA restriction fragments with expression of specific HLA alleles.

pHLA-1 (Fig. 1b, c) contains a 513-base pair (bp) cDNA insert which corresponds to the COOH-terminal 46 amino acids of an HLA class I heavy chain plus a portion of the 3'-noncoding region of the mRNA³. To make a preliminary estimate of HLA class I gene family size, genomic DNA was isolated from a heterozygous LCL, 721 (Table 1) and probed with pHLA-1. On hybridization, 721 genomic DNA digested with the restriction enzyme, HindIII, contained 12 distinct bands (Fig. 2a) which ranged in size from 29 to 1.7 kilobases (kb) and differed

At least three factors contribute to the number of bands of genomic DNA that hybridize with pHLA-1 and thereby affect

Present addresses: Institut für Genetik, der Universität zu Köln, 5000 Koln 41, FRG (H.L.P.); Department of Genetics, Stanford University, Stanford, California 94305, USA (P.K.)

our estimate of the number of class I loci. First, despite the fact that the restriction enzyme used does not cut within the cloned pHLA sequence, it might cut at sites within intervening sequences that separate parts of the pHLA-1 sequence in genomic DNA. Thus, enzymatic treatment could yield two or more fragments derived from a single gene that hybridize with pHLA-1. Second, because the bands which hybridize pHLA-1 differ markedly in intensity, it is possible that the more intense bands represent multiple distinct genes or gene copies. Third, some class I genes may not hybridize with pHLA-1 although this seems unlikely as the amino acid sequence homology¹¹ (88%) between HLA-B7 and HLA-A2 for a significant portion of the heavy chain represented by the coding region of pHLA-1 suggests that the sequence of this region of HLA class I antigens is highly conserved.

Lack of information about the three points above prevents a direct determination of the number of class I genes in the human MHC from the genomic DNA hybridization pattern of pHLA-1. To what extent pHLA-1-positive *Hind*III bands of LCL 721 (Fig. 2a) represent class I loci in addition to *HLA-A*, -B and -C, for example, human analogues¹²⁻¹⁴ of mouse *TL* (ref. 15) and *Qa-2* (ref. 16), or multiple copies of *HLA-A*, -B and -C genes within a haplotype, will require analysis of the corresponding genomic clones. Furthermore, the lack of substantial amino acid sequence information for most *HLA* alleles makes the correlation of genomic clones with allelic specificities exceedingly difficult.

We investigated the usefulness of γ -ray-induced HLA loss mutants for identifying bands in Southern blots with specific HLA loci and their alleles by probing DNA from several such mutants of LCL 721 (Table 1) with pHLA-1. Figure 2 shows the banding pattern found after hybridization of HindIII-digested DNA from six mutants with nick-translated 17 pHLA-1. Four of the mutants had banding patterns that differed from that of the parental LCL 721 cells by either a loss or gain of a band.

Mutant 721.4, a *HLA-B8* loss mutant (Table 1), has every band found in LCL 721 and a new 1.4-kb band not found in LCL 721 that could be explained by a deletion within a larger normal *HindIII* fragment. (Comparison of the digest of 721.4 with those of LCL 721 and 721.18 suggests that possible candidates for the larger band are the 23.5-kb and 1.7-kb bands. These interpretations can be tested by cloning the 1.4-kb fragment and using it to probe the other *HindIII* fragments.)

Simultaneous losses of expression of *HLA-A1*, -B8 and -DR3 are associated with a microscopically visible deletion on

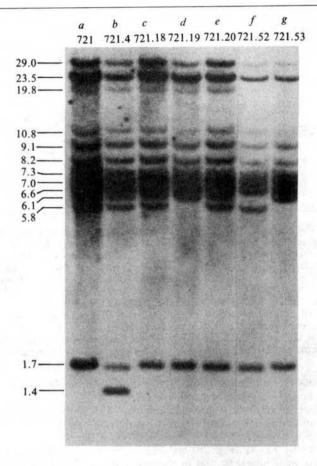

Fig. 2 Southern blot analysis of restriction endonuclease HindIII-digested genomic DNA from LCL 721 and some HLA loss mutants. 15 μg of cellular DNA, isolated as described elsewhere 18, plus 2 μg of λ DNA as a control for digestion, were digested for 18 h with 30 units of HindIII, electrophoresed on a 0.7% agarose, and blotted by the Southern procedure 19. The filter was baked for 2 h at 80 °C in a vacuum oven. Pre-hybridization was in 10 ml of 50 mM NaPO₄ pH 6.5, 50% formamide, 5 × SSC, 5 × Denhardt's 21, 1% glycine and 500 μg ml 3 salmon sperm DNA at 42 °C for 18 h. Hybridization was in 10 ml of 20 mM Na phosphate pH 6.5, 50% formamide, 1 × SSC, 5 × Denhardt's, 100 μg ml salmon sperm DNA, 10% dextran sulphate and 10 c.p.m. of nick-translated 17 pHLA-1 cDNA (specific activity 1.5 × 108 c.p.m. 32 P per μg) for 16 h at 42 °C. The filter was then washed in 1 × SSC for 1 h at 45 °C. Hybridizing bands were detected by autoradiography at -80 °C with a Dupont Lightning-Plus intensifying screen. Sizes of hybridizing bands are in kilobases based on the HindIII fragments of λ. Sources of DNA: Lane a, parental LCL 721; b, 721.4; c, 721.18; d, 721.19; e, 721.20; f, 721.52; g, 721.53. For HLA phenotypes see Table 1.

one chromosome 6 in mutant 721.199. Mutant 721.53, which was derived from 721.19 by γ-ray irradiation and selection for cells that no longer expressed HLA-B5, still expresses HLA-A2 and can be regarded as a HLA-B null mutant. Hybridization of pHLA-1 to HindIII-digested DNA from mutants 721.19 (Fig. 2d) and 721.53 (Fig. 2g) resulted in apparently identical banding patterns. Each mutant lost a 5.8-kb pHLA-1 hybridizing band that is present in LCL 721. Because both mutants have lost only the 5.8-kb band, its absence is correlated with the loss of HLA-B5 expression in 721.53. The 5.8-kb band is present in the HLA-B8 loss variants 721.4, -0.18 and -0.20. Therefore, the absence of the 5.8-kb band is more closely associated with the loss of HLA-A1 expression than of HLA-B8 expression. The other mutant which lost a pHLA-1 hybridizing band was the HLA-A2, -B5, -DR1 loss mutant 721.52 (Fig. 2f). Compared with the 721 banding pattern, 721.52 has lost the 6.1-kb band. The loss of the 5.8-kb band in 721.19 compared with the loss of the 6.1-kb band in 721.52

Table 1 The HLA phenotype of LCL 721 and seven mutants isolated by immunoselection after irradiation of LCL 721 with γ-rays

18	+	_	+	+	+	+
20	+	_	+	+	+	+
19	_	_	_	+	+	+
52	+	+	+	_	_	_
53	_	_	-	+	_	+

The origin of LCL 721 and the procedures for inducing, isolating and characterizing mutants are described in ref. 9. A detailed description of the isolation of mutants 721.52 and 721.53 will appear elsewhere (R. DeM., in preparation). + Refers to expression of marker alleles. 721 and the mother of 721 were typed for HLA-C (C1-C6). Both expressed HLA-C1 only. Mutant 721.52 did not express HLA-C1. This mutant lost expression of the HLA-A2, HLA-B5 haplotype, inherited from the mother, and still expresses HLA-A1 and HLA-B8. We conclude that 721 is heterozygous for HLA-C. HLA-C1 is inherited from the mother on the HLA-A2, HLA-B5 haplotype and something not definable from the father on the HLA-A1, HLA-B8 haplotype.

shows that allelic variations within the HLA complex can be detected by a restriction endonuclease.

Loss of HLA-B5 expression in mutant 721.53 did not result in an additional loss of pHLA-1 hybridizing bands in 721.53 relative to mutant 721.19. Moreover, two of the HLA-B8 loss mutants, 721.18 (Fig. 2c) and 721.20 (Fig. 2e), had banding patterns identical to that of the parental line. The failure to detect alterations in these cases could result from DNA deletions that were too small to detect with our methods or that occurred in HindIII fragments that do not hybridize with pHLA-1. Alternatively, these lines may carry mutations that are not deletions, at least in the coding region of this gene(s). As pHLA-1 corresponds to only the COOH-terminal part of an HLA heavy chain and the 3'-noncoding region of the mRNA, substantial portions of an HLA class I gene could be missed when pHLA-1 is used as the probe. Probing with a nearly full-length HLA cDNA clone⁴ should reveal deletions in the remainder of the gene(s).

Detectable differences in intensity of some bands were also found. As evident from the ethidium bromide staining, some of these are likely to be due to slight differences in the amounts of DNA loaded. For example, more 721 DNA was loaded than from any of the mutants. However, equal amounts of DNA were loaded from mutants 721.18, 721.19 and 721.20 (Fig. 2, c-e). The decreased intensities of the 6.6-10.8-kb bands in 721.19 compared with those in 721.18 and 721.20 are, therefore, consistent with a greater loss of DNA in 721.19 than in 721.18 and 721.20; a complete haplotype in 721.19 compared with a single HLA-B allele in 721.18 and 721.20 (Table 1).

The results described here show the usefulness of using loss mutants in combination with a cDNA probe, pHLA-1, in analysing the organization of the human MHC. They support the concept that HLA class I genes are a multigene family. Similar results have been reported for the H-2 class I gene family in inbred strains of mice^{6,8}. In this regard, note that mutant 721.19 had 11 of 12 pHLA-1 hybridizing bands found in 721. As this mutant has lost one complete HLA haplotype (from HLA-A to HLA-DR), it illustrates that heterozygosity at these loci in 721 has little effect on the number of HindIII bands detected with pHLA-1. The usefulness of radiationinduced HLA loss variants in the analysis of MHC structure is highlighted by the fact that of six variants analysed with one restriction enzyme and a single cDNA probe, three different alterations in the hybridization pattern were detected. Such alterations are not peculiar to HindIII. DNAs from mutants 721.19, 721.52 and 721.53 were also digested with PvuII, PsfI and Sst before probing with pHLA-1. The loss of a pHLA-1 hybridizing fragment was observed with each mutant and all the restriction enzymes (data not shown).

It was conceivable that the pHLA-1 hybridization pattern observed after digestion of DNA with HindIII resulted from reassociation of the 3'-untranslated portion of pHLA-13 with a moderately repeated noncoding DNA sequence. Therefore, a HindIII digest of LCL 721 DNA was probed with a 600-bp fragment containing only the NH2-terminal coding sequence of a nearly full-length HLA cDNA clone⁴. The results show that those pHLA-1-positive bands that are absent in mutants 721.19, 721.52 and 721.53 include the NH₂-terminal sequence (data not shown). Therefore, these bands react with probes for the COOH-terminus and the NH₂-terminus and may contain full-length HLA class I genes. The precise assignment of DNA fragments to specific HLA alleles will require more extensive analyses using newly available mutants, including some that have lost expressions of HLA-A2 alone, HLA-A2 and -B5 or HLA-A1 and -B8, as well as others that are HLA-A-null and HLA-A, -B-null (R. DeM. et al., in preparation).

We acknowledge the help of Mr R. Rudersdorf and Ms C. Chang in the isolation of mutants and the technical help of G. Johnson. This work was supported by NIH research grants AI-15486 (R. DeM. and F.H.B.), AI-17687 (F.H.B.) and AI-10736 (J.L.S.) and by grants from the Leukemia Society of America and the Searle Foundation to H.T.O.

A cloned T-cell line from a tolerant mouse represents a novel antigen-specific suppressor cell type

Joachim Heuer, Karin Brüner, Bertram Opalka & Eckehart Kölsch

Department of Immunology, University of Münster, Domagkstraße 10, 4400 Münster, FRG

Two major alternative models, clonal deletion and suppression, have been proposed as possible explanations for immunological tolerance^{1,2}. We have now isolated a functional T suppressor (T_s) cell clone to analyse the role of T_s cells in the induction and maintenance of tolerance. This cloned, long-term cultured T, cell line (HF1) was derived from CBA/J mice $(H-2^k)$ in which low-zone tolerance (LZT)3 had been induced by subimmunogenic doses of bovine serum albumin (BSA). HF1 cells show BSA-specific suppressor activity in two *in vitro* suppressor assays. HF1 T_a cells and a factor derived from them suppress unprimed, carrier-specific T helper (T_k) cells in an assay measuring IgG antibody production against fluorescein-conjugated BSA (Flu-BSA). Furthermore, they block DNA synthesis in an antigen-specific *in vitro* T-cell proliferation assay. Their proliferation in the presence of antigen-presenting cells is antigen specific and shows restriction to the I-A^k region of the major histocompatibility complex (MHC). In addition, HF1 T_a cells have a characteristic cytotoxic activity. The data reported suggest that clonal deletion and suppression models are not necessarily mutually exclusive. Clonal deletion could manifest itself by the action of T_a cells.

LZT to the antigens BSA and phage fd is accompanied and maintained by T_s cells⁴⁻⁶. Genetic control of LZT induction is, in at least one case, linked to the Igh-1 allotype⁷. To analyse cellular interactions at the molecular level in tolerant animals, it is necessary to produce T-cell lines with specific immunological functions. In an attempt to produce an antigen-specific T_s cell line with the functional properties of T_s cells from low-zone-tolerant mice, CBA/J mice were tolerized by seven consecutive injections of 10 µg BSA per mouse. We anticipated that this sub-immunogenic dose of BSA would activate T_s cells but not T_h cells⁴, and such tolerogenic treatment should therefore preselect T_s cells in vivo and endow them with the capacity to proliferate preferentially on subsequent in vitro selection. After

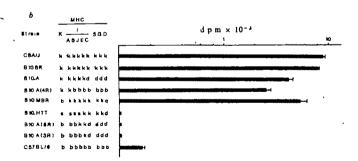

Fig. 1 Antigen specificity and I-A^k restriction in the proliferation of HF1 T_a cells. a, 10⁴ HF1 T_a cells were cultured in 250 μl of DME medium supplemented with 0.5% mouse serum in the presence of 5×10³ 3,000 R measured by addition of BSA or ovalbumm (OVA) and keyhole limpet haemocyanin (KLH) as control antigens. In some experiments BSA-specific proliferation of HF1 T_a cells was inhibited by adding 1 μl monoclonal anti-Ia.m6 antibodies per well. ³H-TdR uptake was measured on day 4 of culture as described in Table 2 legend. b, 10⁴ HF1 T_a cells were cultured in 200 μl DME medium supplemented with 10% FCS and 10% CM in the presence of 5×10⁵ 3,000 R irradiated spleen cells from various congeneic mouse strains, allowing mapping of I-A^k restriction. Proliferation of HF1 T_a cells was measured by ³H-TdR uptake on day 5 of culture as described in Table 2 legend.

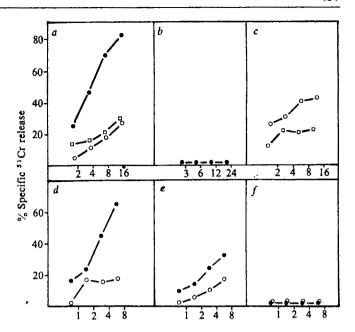

Fig. 2 Cytotoxicity of clone HF1 and subclone HF1.17 T_a ceils against various target cells. Cytotoxicity was measured in a 6-h ⁵¹Cr-release assay using 2×10⁴ target cells per microtitre plate well. Per cent specific ⁵ release is plotted on the ordinate against the effector/target cell ratios on the abscissa. $a_1 \times 10^7$ CBA spleen cells per ml were stimulated with 5 µg mi⁻¹ Con A in DME medium with 10% FCS for 2 days. Cells were washed once in balanced salt solution containing 10 μg mi⁻¹ α -methylmannoside and cultured 1 day longer in DME medium with 10% FCS in the presence of 5% CM. Lymphoblasts were purified on a Fleoil gradient, then labelled with ⁵¹Cr in the form of sodium chromate and used as target cells. HF1

T, cells were tested in the absence (O) or presence (•) of 10 µg mi⁻¹ Con A. Target cell killing is observed in the absence of Con A but can be enhanced in the presence of Con A. HF1.17 cells were tested in the absence of Con A (

). b, C57Bl/6 EL4 T-lymphoma cells were used as targets. HF1 T_a cells cannot lyse these targets even in the presence (●) of Con A. This is an important finding because clone HF1 does not behave like Ta cells, which type target cells nonspecifically in the presence of Con A. c, 2×10^7 CBA spleen cells per ml were cultured for 3 days in DME medium with 10% FCS in the presence of 40 µg ml⁻¹ LPS. Lymphoblasts were purified on a Ficoll gradient and used as target cells. Killing by HF1 (O) and HF1.17 ([]) T, cells is shown. Target cells used in the killing by HF1.17 T_a cells were further purified after Ficoll gradient separation by incubation on anti-Thy-1.2-coated Petri dishes. Non-adherent cells (>98% Ig⁺) were used in the ⁵¹Cr-release assay. d, BSA-specific long-term cultured T cells (LNC-BSA) were derived from lymph node cells of BSA-primed CBA/J mice. They were used as target cells and assayed for killing by HF1 T, cells in the absence (O) or presence (O) of Con A. e, A BSA-specific T-cell clone (LNC-BSA.D.10) derived from LNC-BSA cells was used as target. Assay was in the absence (O) or presence (I) of Con A. f, A HGG-specific long-term cultured T-cell line (LNC-HGG) was used as target cells in the absence (O) or presence (O) of Con A. Lysis of LNC-BSA (e) but not of LNC-HGG (f) cells by clone HF1 cells suggests antigen specificity in killing.

the last in vivo antigenic treatment, splenic T cells were enriched by removing B cells on antibody-coated Petri dishes⁸. They were stimulated with antigen in bulk culture for 4 days and then cloned in soft agar⁹. HF1 cells were derived from 1 out of more than 100 colonies growing, and expanded. We have so far avoided virus transformation¹⁰ or T-cell hybridoma production¹¹ so as to study cellular functions both in terms of cellular interactions and factor production. The following surface characteristics were assessed in indirect immunofluorescence staining tests using fluorescein-conjugated rabbit antimouse or anti-rat immunoglobulin antibodies (Nordic): Thy-1.2⁺ (as defined by an AKR anti-CBA antiserum; Searle); Lyt-1⁻, 2⁺ (as defined by monoclonal antibodies, clones 53-7.3 and 53-6.7; Becton Dickinson); I-A^{k+} and I-E^{k+} (using monoclonal antibodies against Ia.m6, clone H 116-32.R5, and against Ia.m7, clone 13/4.R5; Camon). No I-J^k determinants could be detected by functionally active anti-I-J^k sera¹² from B10.A(3R) mice immunized with B10.A.(5R) lymph node and spleen cells.

T, line HF1 was produced in March 1980 in the following way. For induction of LZT to BSA, CBA/J mice received 2.5 mg hydrocortsone followed by seven consecutive injections of 10 μg BSA per mouse intraperitoneally (1,p.)². One day after the last tolerogenic dose, splenic cells were incubated on Petri dishes coated with rabbit anti-mouse immunoglobulin antibodies. The non-adherent T cells were removed and cultured in Costar plates (1.5×10⁶ cells per well) in the presence of syngencic 3,000 R irradiated spleen cells (5×10⁵ cells per well) in a final volume of 1 ml Dulbecco's modified Eagle's (DME) medium supplemented with 5×10⁻⁵ M 2-mercaptoethanol, 2 mM glutamine, 100 U ml⁻¹ penicillin, 100 μg ml⁻¹ streptomycin (DME medium) and 10% heat-inactivated horse serum (HS). At the beginning of culture, 10 μg BSA per ml were added to restimulate presumptive T, cells in vitro. Four days later growing cells were cloned in soft agar⁹. On day 3 the agar was overlayered with 250 μl of a supernatant from Con A-atimulated rat spleen cells (conditioned medium, GM)²⁰ One to two weeks after starting the cloning procedure, colonies containing 40–100 cells were transferred to flat-bottomed microtitre wells and cultured in the presence of antigen (10 μg BSA per ml), 3×10⁴ syngeneic 3,000 R irradiated spleen cells and 10% CM in the same medium as described above. Cell cultures were fed every 3–4 days with antigen, 3,000 R irradiated syngeneic squence cells and CM. After 4–6 weeks of continuous cell growth, proliferating cells were expanded on Costar plates or in Falcon 3013 tissue culture flasis. Instead of 10% HS and 10 μg ml⁻¹ BSA, 10% heat-inactivated fetal calf serum (FCS) (containing BSA as antigen) was now used. HF1 cells can be frozen in liquid N₂ and thawed with recovery of growth and function. Suppressor activity of HF1 cells was tested in an *in vitro* assay with Flu-BSA as antigen. This assay has been developed as to have an IgG *in vitro* response which depends on primary T_b-cell activation: CBA/J m

* Equivalent to 1×10⁵ cells.

BSA primed	0.6 µg Con A	Anti-Ia.m6 1:250	$99,044 \pm 2,281$

The T-cell proliferation assay using inguinal lymph node cells from antigenprimed CBA/J mice was used as described elsewhere 13, 2×105 lymph node cells were cultured in flat-bottomed microtitre wells with 3×10⁵ 3,000 R ırradiated syngeneic spleen cells in 250 μl of DME medium containing 0.5% mouse serum. At the beginning of culture they were stimulated with either 25 ug heat-aggregated BSA (cBSA) or 100 µg HGG (expt 1) and 500 µg BSA or 0.6 µg Con A (expt 2) per well. Antigen-specific suppressor activity of HF1 cells was determined by addition of 2×10⁴ or 3×10⁴ cells per well. The same degree of suppression was also demonstrated if HF1 cells were treated with mitomycin C before addition to culture (data not shown). Monocional anti-Ia m6 antibodies (1 µl per well) were added to demonstrate its influence on BSA-specific T-cell proliferation. Proliferation was measured on day 4 by pulsing the culture with 0.4 μCl ³Hthymidine (3H-TdR) for 16 h and measuring 3H-TdR uptake. For each experimental condition three independent cultures were set up and mean d.p.m. ±s.d. are given. Lymph node cells were taken from CBA/J mice immunized with 1 mg BSA or 1 mg HGG per mouse in CFA subcutaneously at the base of the tail. Animals were not used until 10 days after immunization.

HF1 cells are Ig⁻ (direct immunofluorescence staining with fluorescein-labelled rabbit anti-mouse Ig antibodies) and FcR⁻(binding of aggregated fluoresceinated human globulin, Flu-HGG).

HF1 T_s cells are functionally active, as demonstrated by suppression of IgG but not IgM anti-Flu antibody production after stimulation with Flu-BSA in an in vitro suppressor assay using unprimed T_h cells and Flu-primed B cells. This suppression is comparable with the effect of BSA-specific T, cells from LZT mice (Table 1). In an independent assay, HF1 cells suppressed antigen-specific BSA-induced in vitro proliferation of lymph node cells¹³ from BSA-primed CBA/J mice. This antigen-specific proliferation was also inhibited by monoclonal anti-I-Ak antibodies in place of HF1 Te cells, indicating that stimulation is I-Ak restricted (Table 2). This BSA-induced in vitro T-cell proliferation assay was used to analyse subclones of HF1 T, cells. HF1 T, cells were subcloned by limiting dilution microculture (1 and 0.3 cells per microplate well) in the same culture conditions as described in Fig. 1b legend. Plating efficiencies ranged from 70 to 100%. All 22 subclones expanded and tested for functional activity showed suppressive activity (data not shown), indicating that HF1 T, cells represent a homogeneous population.

Restriction analysis was performed to identify genes of the H-2 region which regulated proliferation of HF1 T_s cells in the presence of antigen. We first established that the proliferation of HF1 T_s cells requires antigen in the presence of irradiated syngeneic stimulator cells (Fig. 1). This proliferation can be inhibited by supplementing the cultures with monoclonal anti-I-A^k antibodies. Mapping experiments show that their proliferative response is restricted to I-A^k recognition in the MHC. An influence of the I-J^k region is excluded (Fig. 1).

I-A' determinants on HF1 T, cells can be labelled biosynthetically using ³⁵S-methionine (unpublished data), showing that they are synthesized by HF1 T, cells themselves. These data might be a key to understanding differences in the antigendependent activation processes of T_h and T_e cells. Expression of I-A determinants on cloned T_h cells has not been found, but available evidence from heterogeneous Th-cell populations suggests that there is little expression of I-A determinants on these cells.¹⁴ One could envisage a competitive intervention of T_e cells in the interaction between antigen-presenting, I-A determinant-bearing macrophages and T_h cells. The suppressor effect of HF1 T, cells can also be demonstrated using cell-free supernatants from HF1 T, cells. The factor both suppresses IgG anti-Flu antibody production in vitro on challenge with Flu-BSA (Table 1) and inhibits BSA-specific T-cell proliferation (data not shown). The factor has not been analysed in detail and it remains to be seen whether it is different from the suppressor factor produced by a T_s-cell clone from hyperimmune mice15

The additional cytotoxic activity of HF1 T, cells (Fig. 2) distinguishes them from all other T_s-cell lines described so far. HF1 T_s cells can kill concanavalin A (Con A)- or lipopolyssacharide (LPS)-stimulated syngeneic spleen cells but not allogeneic target cells, even in the presence of Con A. Cytotoxic T (T_c) cells nonspecifically lyse target cells in the presence of Con A, due to cell-cell bridging^{16,17}. This implies that the mechanism of cytolysis through HF1 T, cells is different from T_c cell activity.

Subclone HF1.17 isolated from microcultures seeded with an average of 0.3 HF1 cells per well has cytotoxic activity (Fig. 2) and produces a suppressive factor (Table 1). As we were unable to demonstrate cytolysis by the factor itself, a cloned cell of the HF1 T, line must possess two functional properties, factor-mediated suppression and cell-mediated cytolysis.

In considering implications of the above findings for possible mechanisms of immunological tolerance, one must be aware that no definite proof has been found for the absence of T, cells in cases of apparent clonal deletion 18. A presumed incompatibility of the extremes of suppression and deletion models is conceptually largely based on the assumption that clonal deletion is due to a direct interaction of antigen with the cell to be rendered tolerant19. Our finding of a novel type of T, cell clone provides an experimental basis for a combination of both models, suggesting that clonal deletion could be a consequence of T, activity.

We thank Ms P. Wippern for technical assistance and Mrs H. Storkebaum for preparing the manuscript. The work was supported by DFG grants Ko 379/9-10.

Mouse spleen and IgD-secreting plasmacytomas contain multiple IgD δ chain RNAs

Immunoglobulin gene expression requires that cells combine the correct genetic information by DNA rearrangement and RNA processing to produce mature, translatable mRNAs. The mechanisms that operate to produce IgD heavy chain (δ chain) mRNA are thought to be especially complex1-3. Like other immunoglobulins, IgD exists in membrane and secreted forms^{4,5}. By analogy with results of studies of μ^{6-10} and $\gamma^{11,12}$ gene expression, we expected that δ chains would also be encoded by two different mRNAs, containing common sequence information transcribed from constant region gene segments but different information transcribed from coding sequences located 3' to the constant region gene segments. Instead, we identified¹³ more than two δ mRNAs in normal mouse spleen and in two IgD-secreting plasmacytomas¹⁴, TEPC 1017 and TEPC 1033. Now we have used 32P-labelled DNA fragments prepared from a δ cDNA clone¹⁸ and a δ genomic clone ¹⁶ to characterize by hybridization these δ RNAs, fractionated on methyl mercury hydroxide agarose gels. We find that normal mouse spleen contains a major 2.9-kilobase (kb) and a minor 2.1-kb RNA encoding membrane-bound δ chains (δ_m) and that TEPC 1017 and TEPC 1033 contain similar $\delta_{\rm m}$ RNAs plus a 1.75-kb RNA encoding secreted δ chains (δ_s). We have also observed less abundant δ RNA species (2.65 and 3.2 kb). Different gene segments or combinations of segments are used in the 3' termini of the multiple δ RNAs.

The δ chain synthesized by normal spleen cells bearing IgD on their surface is presumed to be derived from a complex transcription unit, including a rearranged μ gene^{1-3,17}. In contrast, synthesis of δ chain for secreted IgD is postulated to require deletion of the μ gene^{1-3,17}. Figure 1 shows that TEPC 1017 contains most of its constant domains on a 3.3-kilobase pair (kbp) HindIII fragment, which is smaller than that of liver (4.0 kbp), and that TEPC 1033 contains its δ on a larger (4.6 kbp) fragment. These data are compatible with the relocation of different V-D-J complexes 5' to the C81 domain, between the HindIII site 2.0 kbp 5' to Co1 and the EcoRI site

0.5 kbp 5' to Cδ1 in these plasmacytomas¹⁶

DNA rearrangements 3' to expressed constant region genes have also been reported in plasmacytomas¹⁸, though only rarely. Figure 1 demonstrates that $C\delta$ genes in liver and both plasmacytomas are contained in a single 9.8-kbp EcoRI fragment. This fragment, which was isolated from BALB/c liver and cloned, has previously been shown to contain the C δ gene segments 16 plus virtually all the 3' gene segments to be discussed here 17. Thus, no detectable rearrangements 3' to the δ constant domains have occurred in these tumours, although the possibility of small deletions or rearrangements within the 9.8-kbp fragment cannot be excluded. We assume that (1) this portion of the DNA is identical in liver, the IgD-secreting plasmacytomas and IgD-bearing cells in normal spleen; and (2)

all the δ RNAs we observe in the plasmacytomas and in normal spleen are derived from δ gene transcription units identical in their 3' sequence to that found in liver DNA

The 1.75-kb δ RNA identified in TEPC 1017 and TEPC 1033 RNA is the most abundant δ RNA in these plasmacytomas and is not detected in normal spleen RNA (Fig. 2a). Both plasmacytomas secrete large amounts of IgD protein14; spleen cells bear IgD on their surfaces but fewer than 1 in 105 cells secrete IgD19. Thus, it is likely that the 1.75-kb RNA species is mRNA encoding δ chain for secreted IgD and that one or more of the less abundant δ RNA species in plasmacytomas are mRNAs encoding δ chain for membrane-bound IgD.

The hybridization data presented in Fig. 2 and summarized in Fig. 3 show that the only gene segment to the 3' side of $C\delta 3$ represented in the 1.75-kb δ RNA is contained in the DC1 fragment. DNA sequence data1 reveal that the exon contained in the DC1 fragment encodes a non-hydrophobic polypeptide consistent with the carboxy-terminal sequence of a secreted form of heavy chain.

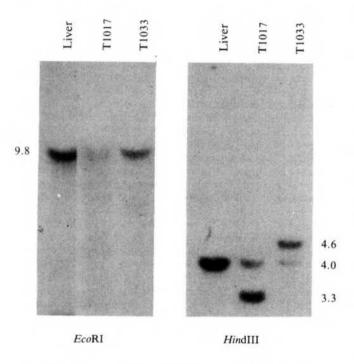

Fig. 1 Cδ hybridization analysis of EcoRI- and HindIII-digested genomic DNA from BALB/c mouse liver and TEPC 1017 and TEPC 1033 tumours. Fragments generated by digestion of 25 µg of each DNA were fractionated by electrophoresis in 0.7% agarose gels, denatured in alkali, neutralized and transferred to a sheet of nitrocellulose²⁴. The sheet was hybridized to a 563-bp DNA fragment (containing only $C\delta$ sequences) that had been excised from p δ 54J plasmid¹⁵ by digestion with PvuII and HindIII, purified by electrophoresis on a 4% polyacrylamide gel²⁵ and labelled with ³²P by nick-translation²⁶ to 1.0×10^8 c.p.m. μg^{-1} of which 2.5×10^6 c.p.m. were used in 25 ml hybridization solution. Lengths of hybridizing fragments (in kbp) were determined by comparison with ethidium bromide-stained EcoRI and HindIII fragments of phage & DNA and are indicated. The pattern of δ-hybridizing fragments in liver DNA is consistent with the previously published restriction map of the δ gene cloned from BALB/c liver 16; immunoglobulin genes in liver DNA are assumed to remain in germ-line configuration. Both tumours have ~25% of their δ DNA in the form seen in liver as determined by densitometric scanning of the autoradiogram. Both plasmacytomas are pseudotetraploid (G. Klein and S. Ohno, personal communication), and it seems likely that one of the four chromosomes remains unrearranged while the other three have undergone rearrangement. However, because the plasmacytoma DNAs were prepared from solid tumours, it is possible that contaminating normal tissue contributed some or all of the unrearranged genes seen in these digests.

The only other δ RNA species that hybridizes with DC1 is the much less abundant 3.2-kb δ RNA in TEPC 1017 and TEPC 1033 (Fig. 2c). This RNA also hybridizes with the AC1 probe (Fig. 2b), and it may represent a short-lived precursor of the 1.75-kb δ_s mRNA.

Membrane IgD is present on most splenic B cells20 and on TEPC 1017 and TEPC 1033 (ref. 14). We presumed that δ_m mRNA would be the most abundant δ RNA in spleen as well as being readily detectable in RNA from these plasmacytomas. The 2.9-kb δ RNA meets these criteria (Fig. 2a) and probably encodes δ chain for membrane IgD. This 2.9-kb δ_m mRNA hybridizes with VDC1 (Fig. 2e) and VDC2 (Fig. 2f) but not with DC1 (Fig. 2c). The DNA sequence 17 of VDC1 encodes a hydrophobic polypeptide ~50% homologous to the amino acid sequence of the δ_m transmembrane polypeptide. This is further evidence that the 2.9-kb δ RNA is a form of δ_m mRNA.

A less abundant δ RNA (2.1-kb) in the plasmacytomas and in spleen also hybridizes with VDC1 sequences. It probably represents another form of δ_m mRNA lacking sequences encoded in VDC2 (Fig. 2f) or VDC3 (data not shown) which are found in the 2.9-kb δ_m mRNA.

Whereas the 2.9-kb δ RNA in the plasmacytomas hybridizes with AC1 (Fig. 2b), the 2.9-kb δ RNA from spleen does not. Thus, plasmacytoma cells may contain at least two δ RNAs in the 2.9-kb band: one (containing AC1 sequences) may be a precursor of the 2.1-kb δ_m mRNA, and another (similar to that in spleen) may be an alternative form of δ_m RNA containing a different 3'-untranslated region.

The 3.2-kb δ RNA species is rare in both spleen and plasmacytomas. As discussed above, in the plasmacytomas it appears to be a form of δ_s RNA. The 3.2-kb δ RNA in the spleen hybridizes with VDC1, VDC2 and VDC3 (Fig. 2e, f) but not with DC1 (Fig. 2c), suggesting that it is a form of δ_m RNA, either a third mature form of δ_m mRNA in the spleen, or a precursor of one of the other two δ_m mRNAs.

The DC2 probe hybridizes (Fig. 2d) with a 2.65-kb RNA species but with none of the other δ RNAs described here. The amount of the 2.65-kb RNA species varies among different preparations of plasmacytoma and spleen RNA and is by far the least abundant δ RNA detected. Thus the composition of this δ RNA with respect to other DC, AC or VDC sequences

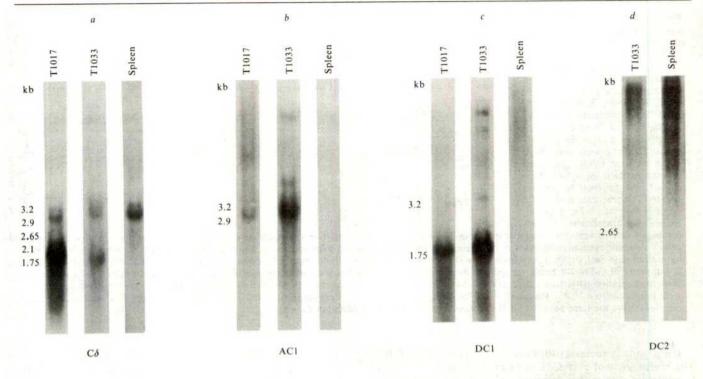

and its possible function cannot yet be stated.

Our studies of normal spleen and two IgD-secreting plasmacytomas suggest that δ chain is unusual among immunoglobulins in that its mRNAs exist in so many forms. While some of these δ RNAs may represent aberrant transcripts analogous to the 'C, RNAs' described by others21,22, their presence in normal spleen argues against their being abnormal. Preliminary experiments have identified the 2.1-, 2.9- and 3.2-kb δ RNAs on polyribosomes prepared from B-cell lymphomas which also indicates that all three are normal, functional mRNAs. The complexity of the δ gene transcripts contrasts with the mouse IgM8,9 and IgG11,12 heavy chains, each of which is encoded by only two mRNAs, one for the membrane form and one for the secreted form of the protein.

Other groups^{2,3} have studied δ RNA in B-cell tumours and hybridomas, but none has reported the complex array of δ RNAs identified here in normal spleen and plasmacytomas. The 1.8-kb δ RNA reported by these groups is probably identical to the δ_s mRNA we report. Similarly, their 2.7-kb mRNAs^{2,3} may be identical to the 2.9-kb δ_m mRNAs we report here. The less abundant RNAs reported here of 2.65 kb and 3.2 kb have not been described by other groups, although Maki et al.3 noted that R-loops observed but not presented suggested

that there could be other forms of δ RNA.

We have identified δ RNAs in spleen and TEPC 1017 and TEPC 1033 which encode the membrane form(s) of δ chain and share certain significant characteristics. Most important, a hydrophobic (transmembrane) polypeptide17 is encoded in both the 2.9- and the 2.1-kb δ_m mRNAs found in spleen and the plasmacytomas. In addition, the 2.9-kb δ_m mRNAs from both sources contain sequences encoded in VDC2 and VDC3.

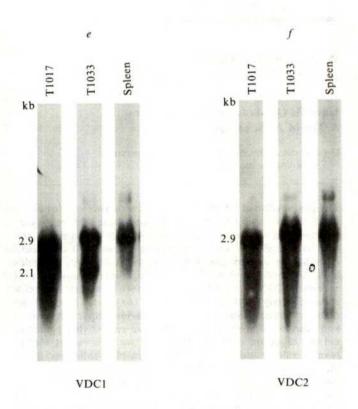

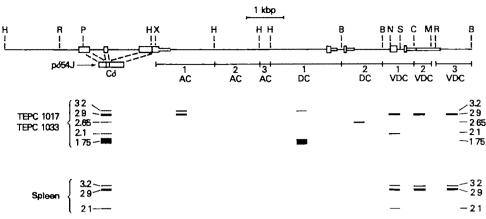

Fig. 2 Hybridization analysis of poly(A)+ RNAs prepared from IgD-secreting plasmacytomas and normal spleen. Cytoplasmic RNA was prepared as described previously¹⁵ from TEPC 1033 ascites cells which had been maintained in tissue culture. Total cellular RNA was prepared by homogenizing pulverized frozen plasmacytoma tumours or BALB/c spleens in 4 M guanidinium thiocyanate and precipitating with ethanol²⁷. Total cellular RNA also was prepared from spleen by a LiCl-urea extraction procedure²⁸. Poly(A)⁺ RNA was prepared by selection on oligo(dT)cellulose and treated with methyl mercury hydroxide before being fractionated on 1% (or 0.7% in the case of b and TEPC 1017 lanes in e and f) agarose gels containing 5.0 mM methyl mercury hydroxide²⁹. RNA was leaded at 5 μ g per lane. TEPC 1033 poly(A)+ RNAs in b and c were prepared from total cytoplasmic RNA; spleen poly(A)+ RNA in d-f was prepared from total cellular RNA isolated by the LiCl-urea extraction procedure. All other poly(A)+ RNAs shown were derived from total cellular RNAs prepared by the guanidinium thiocyanate extraction procedure. Following electrophoresis, the RNA transfer and hybridiz-ation was carried out as described elsewhere 30,31 except that DPT was used instead of diazobenzyloxymethyl paper. The restriction fragments (see Fig. 3) used for nick-translation were isolated from polyacrylamide gels²⁵. The specific activities of the 32 P-labelled probes ranged from 2×10^7 to 4×10^8 c.p.m. μg^{-1} ; 106 c.p.m. ml⁻¹ of hybridization mixture were used. The probes described in Fig. 3 were each hybridized to a set of lanes containing the RNA from TEPC 1017, TEPC 1033 and spleen cells (a, Cδ; b, AC1; c, DC1; d, DC2 (which required an unusually long exposure time); e, VDC1; f, VDC2). The approximate sizes of the hybridizing species (in kb) discussed here are shown to the left of each panel and were determined by reference to ethidium bromide-stained mouse 18S and 28S rRNAs which were assumed to be 2.0 kb and 4.7 kb respectively³³ and by reference to tobacco mosaic virus (6.34 kb)³⁴ and brome mosaic virus (0.87, 2.3, 3.1, 3.4 kb)35 RNAs fractionated in adjacent lanes.

Different portions of these 'very distant' 3' sequences may be used in the 3'-untranslated regions of these δ_m mRNAs analogous to the variable 3'-untranslated regions of the multiple forms of mRNA for mouse dihydrofolate reductase²³. Alternatively, one or more exons in the sequence may be translated and expressed as alternative or additional 3' polypeptide termini. Such different forms of δ_m chain might thus allow not only a transmembrane 'anchor' for membrane IgD but also one or more internal (cytoplasmic) termini available for different effector functions of IgD. Another possibility is that the multiplicity of δ_m mRNAs represents a redundancy in the δ gene to

ensure that B cells will be able to produce membrane IgD even if genetic accidents interfere with mRNA processing and/or translational pathways.

Note, however, that at least some of the δ_m mRNAs in the plasmacytomas are different from those identified in normal spleen. AC1 and DC1 sequences are readily detectable in the plasmacytoma RNAs but not in normal spleen. The lack of AC1 and DC1 hybridization in spleen RNA probably reflects the fact that spleen primarily synthesizes δ_m and contains very few plasma cells which utilize RNA transcriptional pathways leading to δ_s expression. It has been postulated^{2,3} that deletion

Fig. 3 Restriction enzyme map showing the BALB/c δ gene¹⁶ and the genomic fragments subcloned from it. B, BamHI; C, ClaI; H, HindIII; M, MboI (converted to BamHI when inserted into Charon 28 phage clone); N, HincII; P PvuII; R, EcoRI; S, RsaI; and X, Xbal. The restriction enzyme map and the boxes defining δ exons are described in greater detail elsewhere 16,17. Fragments from phage clones of liver DNA 16 indicated diagrammatically here were subcloned into appropriate plasmid vectors. The preparation of the $C\delta$ probe is described in Fig. 1 legend. Before nick-translation²⁶ the re-

combinant DNA fragments were separated from the plasmid vector by restriction endonuclease digestion and fractionation on polyacrylamide . A semiquantitative diagram summarizing the results of repeated experiments in which plasmacytoma RNA or spleen RNA was hybridized with each probe is presented below the name of each probe. Photographs of representative autoradiograms are presented in Fig. 2, but many of the minor bands are difficult to photograph in the presence of other bands which hybridize very strongly. VDC3 gave the same hybridization pattern as VDC2, and AC2 and AC3 did not reveal any discrete bands of hybridization (data not shown). Two fragments were prepared from VDC1 that contain the following sequences: those between HincII and RsaI, or those between RsaI and ClaI. Both fragments gave the same pattern of hybridization as the whole VDC1 (data not shown).

of the μ gene is necessary for cells to synthesize secreted IgD. The rearrangement 5' to $C\delta 1$ in TEPC 1017 and TEPC 1033 is consistent with such a deletion, and it could also alter transcriptional and processing pathways in the δ_m gene complex.

Membrane IgD has long been thought to be important in B-cell development although its exact role remains controversial. As discussed above, the multiple δ_m mRNAs described in this report could represent mRNAs for multiple forms of δ_m protein. Cloning of DNA sequences for these multiple $\delta_{\rm m}$ mRNAs and cell-free translation studies are in progress to help elucidate the biological role of membrane IgD and the regulation of its expression.

We thank Fred D. Finkelman and our colleagues in the NIAID Laboratory of Immunology and the NCI Laboratory of Cell Biology for critical reading of the manuscript. We thank Shirley Starnes for assistance in preparing the manuscript. The work was supported in part by NÎH grants AI 16547 to P.W.T. and GM 21812 to F.R.B.

Xenobiotic conjugation: a novel role for bile acids

Gary B. Quistad, Luana E. Staiger & David A. Schooley

Department of Biochemistry, Zoecon Corporation, 975 California Avenue, Palo Alto, California 94304, USA

The conjugation of foreign compounds with hydrophilic natural products (for example, amino acids, glucuronic acid) represents an important biochemical mechanism of attenuating xenobiotic toxicity and of facilitating excretion of hydrophobic chemicals. Although several conjugation reactions are known¹, bile acids have not been implicated previously in the conjugation of xenobiotics. The physiological importance of natural bile acids is based partly on their propensity to conjugate through their carboxyl groups with several amino acids (especially glycine and taurine), thereby creating effective emulsifying agents to aid the digestion of lipids. However, we now report that in several animal species, bile acids form metabolic conjugates through a hydroxyl group with an acidic metabolite of fluvalinate, a pyrethroid insecticide. Conjugates of this acidic metabolite with cholic, taurochenodeoxycholic and taurocholic acids are major secondary metabolites found in excreta of the cow, chicken and rat, respectively, and represent 5-12% of the faecal 'C-labelled residue.

Fluvalinate (\alpha-cyano-3-phenoxybenzyl 2-(2-chloro-4-trifluoromethylanilino)-3-methylbutanoate; Mavrik) is a pyrethroid insecticide2 that is metabolized primarily by ester hydrolysis to an anilino acid (Table 1 and Fig. 1), and is excreted intact, conjugated with amino acids, or hydroxylated at the isopropyl methyl group^{3,4}. Using TLC and reverse-phase liquid chromatography, we isolated from cow faeces an unknown metabolite of fluvalinate which was identified by mass spectrometry as an anilino acid conjugate of cholic acid (Table 1).

Table 1 Bile acid conjugates of an acidic xenobiotic in animal faeces

				% ¹⁴ C in faeces		
Conjugate	R_1	R ₂	R_3	Rat (0-3 day)	Chicken (0-1 day)	Cow (3–4 day)
Cholate	ОН	OH	O	0.5	< 0.5	8.1*
Chenodeoxycholate	он	H	O		*****	1.3
Deoxycholate	H	ОН	O ⁻			2.2
Taurocholate	OH	ОН	NHCH ₂ CH ₂ SO ₃	5.0	< 0.5	< 0.5
Taurochenodeoxycholate	OH	H	NHCH ₂ CH ₂ SO ₃	3.2	11.9†	< 0.5
Taurodeoxycholate	H	OH	NHCH ₂ CH ₂ SO ₃	< 0.5	< 0.5	< 0.5
Glycocholate	OH	OH	NHCH ₂ CO ₂	< 0.5	< 0.5	0.3
Glycochenodeoxycholate	OH	H	NHCH ₂ CO ₂	< 0.5	< 0.5	0.6
Glycodeoxycholate	H	ОН	NHCH ₂ CO ₂	<0.5	< 0.5	0.2

* The choic acid conjugate when methylated (diazomethane in ether/methanol) displayed the following characteristics. TLC (silica gel GF), $R_F = 0.28$ m ether/hexane (1·1), reverse-phase liquid chromatography (LiChrosorb RP-8 column, acetonitrile/0.1% acetic acid (75·25), flow rate 1.6 ml min⁻¹, UV detection at 254 nm, k' = 12.7); mass spectrum (m/z (relative intensity), electron impact), 701 (1.1, M⁺ for Cl = 37), 699 (3, M⁺ for Cl = 35), 252 (97), 250 (100), mass spectrum (chemical ionization (CH₄)), 728 (5, M+29), 700 (6, M+H for Cl = 35).

The taurochenodeoxycholic acid conjugate (as its methyl ester) was purified by TLC (silica gel GF, ethyl acetate/hexane (2.1)) and reverse-phase liquid chromatography (methanol/0 1% acetic acid (80 20), k'=15 5). It was identified from the following spectral data ¹H NMR (Bruker WM-300, 300 MHz, (CDCl₃)), $\delta=0.66$ (s (singlet), 3, CH₃ at C-18), 0.91 (s, 3, CH₃ at C-19), 1 03 (d (doublet), 3, J=7 Hz, isopropyl CH₃), 1.08 (d, 3, J=7 Hz, isopropyl CH₃); 3.74 (t, 2, J=6 Hz, CH₂SO₃), 3.93 (s, 3, OCH₃), 4 66 (multiplet, 1, H at C-3 of steroid). Field desorption mass spectrum (m/z (relative synthesized for analysis by ¹H NMR spectroscopy (Varian T-60 instrument, CDCl₃) to determine the position of conjugation on the bile acid For each standard the chemical shift of the methine hydrogen in the bile acid at the carbon bearing an acylated hydroxyl was used to diagnose the site of esterification: for the anillino acid conjugate of methyl inthocholate (3β -methine hydrogen only), $\delta=4.80$ p.p.m (broad singlet); for the trisbenzoate of methyl cholate, $\delta=4.82$, 5 38, 5 50 (3β -, 7β - and 12 β -methine hydrogens, respectively); for the bisbenzoate of methyl deoxycholate, $\delta=4.90$ and 5.43 (3β - and 12 β -methine hydrogens, respectively). Together with the broadness of the 3β -methine hydrogen resonance (compared with that of the 7β - and 12 β -hydrogens), these data support our assignment of conjugation at the 3α -hydroxyl monety.

Subsequent comparison with a synthetic standard confirmed this.

The apparent novelty of this bile acid adduct led us to examine the generality of the finding. Most (67%) of the ¹⁴C-labelled metabolite residue in excreta of chickens treated with [CF3-¹⁴Clfluvalinate was highly polar (no migration on silica gel TLC with development in ethyl acetate). However, methylation of this polar 14C-residue with diazomethane gave (in part) a relatively nonpolar product ($R_F = 0.25$ on silica gel GFTLC developed with ethyl acetate/hexane, 2:1). By administering a single oral dose of ¹⁴C-fluvalinate (100 mg per kg) to a Leghorn hen, we purified 300 µg of this metabolite (as its methyl ester) using TLC and reverse-phase liquid chromatography. The metabolite was identified as an anilino acid conjugate of taurochenodeoxycholic acid by ¹H NMR spectroscopy and field desorption mass spectrometry. Acylation of taurochenodeoxycholic acid by the anilino acid occurred at the 3α -hydroxyl group (not the 7α -hydroxyl), as deduced from the ¹H NMR chemical shift of the methine hydrogen at C-3 of the acylated bile acid ($\delta = 4.66 \text{ p.p.m.}$) and its multiplet coupling pattern. A synthetic sample of the conjugate gave an identical NMR spectrum, showing that chemical and metabolic acylation both favour the least hindered 3α -hydroxyl position of the bile acid5.

To determine any additional bile acid conjugates, the remaining common bile acids (as methyl esters) were acylated using

the acyl chloride of the anilino acid, thus providing reference standards for chromatographic comparison. Rats, chickens and a cow were given a single oral dose of fluvalinate at 1 mg per kg; analysis of their excreta by TLC, and reverse-phase and normal-phase liquid chromatography, revealed a general occurrence of these bile acid conjugates (Table 1). The relative abundance of a particular conjugate appeared to be proportional to the composition of the natural bile acids in the animal: for example, taurochenodeoxycholic acid is the major bile acid in chickens while taurocholic and taurochenodeoxycholic acids are most abundant in rats⁶.

The fact that bile acid conjugates of xenobiotics have not been described previously may be explained by the numerous difficulties in manipulating these conjugates. In this study the taurine-containing conjugates were most abundant—these compounds are highly polar because of the free sulphonic acid moiety, adhering tightly to silica gel and even laboratory glassware. Methylation of the sulphonic acid is inefficient and once formed, the methyl ester decomposes slowly whether neat or in acetone solution.

We have described a new, apparently general role for bile acids in the metabolic conjugation of a xenobiotic by a rodent, a ruminant and a bird. Although this example involves a pesticide metabolite, certain drugs (or their acidic metabolites) may be processed similarly. Indeed, normal resorption of these bile acid conjugates may offer an alternative

Fig. 1 Conjugation of fluvalinate to an anilino acid.

explanation for some enterohepatic circulation of foreign com-

We emphasize that these bile acid conjugates are not minor metabolites; collectively they represent 6 and 11% of the administered 14C dose in rats and chickens, respectively. Our suggestion that they have general occurrence is based largely on the promiscuous conjugation of an anilino acid with whatever bile acids predominate in the species investigated. Further studies should test the generality and toxicological ramifications of this excretion mechanism and may also identify previously unknown, intractable metabolic residues.

We thank G. C. Jamieson for mass spectral analysis; Drs M. Maddox and C. Schramm for ¹H NMR analysis; and Drs Y. Naya and H. Naoki for field desorption mass spectrometry.

We examine here the proposition that membrane lipids¹⁻⁴, rather than intrinsic membrane proteins⁵⁻⁷, are the principal structural elements of the strands comprising tight junctions. Our evidence, which is based on direct rapid freezing of newly formed tight junctions between rat prostate epithelial cells, indicates that individual tight junction strands are pairs of inverted cylindrical micelles sandwiched between linear fusions of the external membrane leaflets of adjacent cells. Although individual tight junction strands appear as continuous cylinders when fractured near the frozen surface, where ice crystals have not damaged the plasma membrane, they appear as rows of particles when fractured deeper in the frozen tissue. We now interpret these tight junction particles as remnants of intramembrane cylinders disrupted during freezing The morphology and dimensions of the intact cylinders correspond to those of lipids in the cylindrical hexagonal II phase^{8,9} and this suggests that tight junction formation requires a phase transition of the planar lipid bilayer similar to that invoked in models of membrane fusion^{10,11}. Our morphological interpretation explains the known functional properties of tight junctions.

Tight junction strands have been assumed to consist of a row of intramembrane particles representing integral membrane proteins which on fixation (glutaraldehyde 1-5%) and cryoprotection (glycerol 20-30%) form the continuous fibrils observed in standard freeze-fracture replicas^{5-7,12-16}. This interpretation was based on the observation that a chain of particles replaces the continuous fibrils when the only preparative step is freezing by immersion in liquid Freon—a procedure which freezes tissue more slowly than current rapid freezing methods 12,17. Subsequent studies where mixtures of fibrils and particles were obtained after brief fixation in dilute glutaraldehyde were interpreted to confirm the proteinaceous nature of tight junction strands7. Freeze-fracture has also been used to investigate whether the tight junction strand comprises a single fibril¹⁸ or a pair of fibrils, either lying side by side^{5,14} or, as most recently suggested, offset across the membrane contact⁶.

In the present experiments, fresh tissue was frozen directly with liquid helium in order to minimize the physical effects of ice crystal formation and to avoid the effects of chemical fixation and cryoprotection with glycerol (which may contain contaminants with potential cross-linking properties⁷). Pieces of ventral prostate gland were excised from adult Sprague-Dawley rats under light ether anaesthesia. The slices were incubated for 3-15 min in 0.1 M buffer, pH 7.4, at 37 °C, placed on a rapid freezing stage and frozen with liquid helium by methods described elsewhere¹⁷. During this incubation, new tight junction strands form along the entire length of the lateral plasma membranes of adjacent epithelial cells2.

Near the original surface of the slice, where ice crystals do not impinge on the plasma membrane¹⁷, pairs of cylinders (9-11 nm in diameter) lie side by side along contacts between adjacent bilayers; each cylinder corresponds to a tight junction fibril. The cylinders form elongated segments that adhere to either the protoplasmic (P, Fig. 1a) or the exoplasmic (E, Fig. 1b) fracture face, leaving a complementary furrow on the other fracture face (Fig. 1a,c,d). Where the plane of fracture jumps from an E face of one membrane to the P face of the adjacent membrane two cylinders may be exposed (Fig. 1d) or one cylinder and a groove left by an adjacent cylinder that adhered to the complementary E face (Fig. 1c). For such planes of fracture to occur, the cylinders must be slightly offset with respect to each other⁶. This asymmetric disposition of the cylinders also explains why lateral views at junctional P face-P face transitions between abutting membranes of adjacent cells show only one of the cylinders, regardless of whether the transition is viewed from its apical or basal aspect (Fig. 1e). The diagram of a tight junction strand in Fig. 2a illustrates in cross-section the disposition of the two intramembrane cylinders. Figure 2b shows different observed planes of fracture through such a

Deeper in the frozen tissue, where larger ice crystals impinge on the plasma membrane, cylinders are replaced by chains of particles that always appear on the E faces (Fig. 1f), but still leave continuous grooves on the P faces (Fig. 1g). Short segments of cylinder mixed with rows of particles are found over continuous grooves in both E (Fig. 1h) and P (Fig. 1i) faces of the plasma membrane at intermediate levels of freezing. The chains of particles seen on the E fracture faces of plasma membranes in poorly frozen areas (Fig. 1f) appear to be remnants of disrupted cylinders. Additional evidence that the tight junction strand is not a chain of particles is that a furrow, not a row of punctate depressions, is found on the complementary P face (Fig. 1g).

Although freeze-fracture images are normally analysed on the assumption that particles represent intramembrane proteins, it has recently been demonstrated that membranes made of lipids, which are capable of forming hexagonal II phase, have pits and particles on their freeze-fracture faces 1,11,19-23. Indeed, some published micrographs of protein-free liposomes suggest the presence of elongated cylinders within the lipid bilayers (see Fig. 1b in refs 23 and 24). The intramembrane cylinders at tight junctions have several features, such as hydrophobic environment (interior of the bilayer), morphology (smooth surface) and dimensions (9-11 nm diameter), which resemble those of inverted cylindrical lipid micelles (hexagonal II phase)^{8-10,25-27}, and which suggest that the cylinders found after direct rapid freezing could be differentiated lipidic domains rather than proteinaceous structures embedded in the mem-

Other evidence that tight junction strands are lipidic, rather than chains of protein particles, is (1) cylinders obtained after glutaraldehyde fixation of pancreas or prostate tissues are disrupted after soaking in glycerol4 or acetone (B.K. and T.S.R., unpublished observations) but neither glycerol or acetone

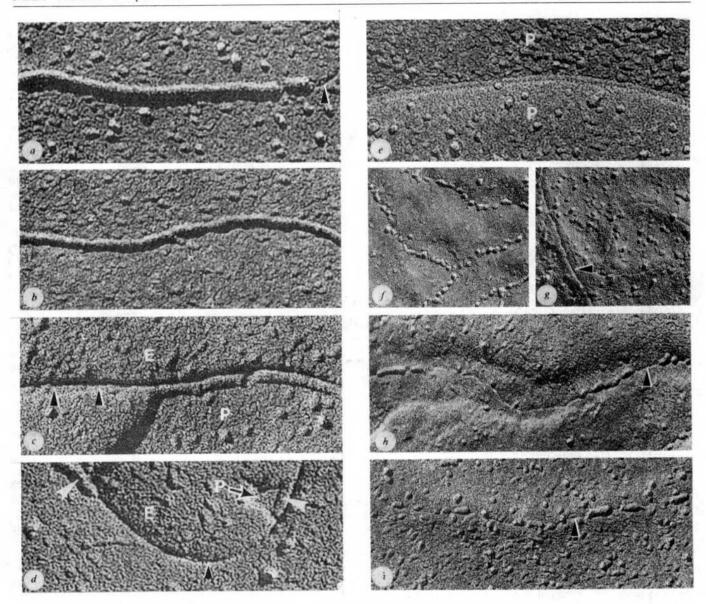

Fig. 1 Tight junction strands on fracture faces of plasma membranes of directly frozen rat ventral prostate epithelial cells. Continuous cylinders are found on P (a, c) and E (b) fracture faces near the original surface of the tissue where ice crystals have not visibly damaged the membranes. Two cylinders, one belonging to each of the pair of membranes participating in the tight junction, are seen in d (white arrowheads). Cylinders are also typically intact at junctional P face-P face transitions at abutting basal portions of plasma membranes of adjacent cells (e). At deeper regions in the specimen, where ice crystals impinge on membrane structure, chains of particles replace cylinders on E fracture faces (f), leaving a continuous groove on P faces (g). Mixtures of particles and short segments of cylinders are found over continuous grooves in both E (h) and P (i) faces from regions of intermediate ice crystal damage. P, P fracture faces; E, E fracture faces; (g) point to continuous grooves. Platinum deposits are white. (g) and (g) and (g) and (g) and (g) are (g) and (g) are (g) and (g) and (g) and (g) are (g) are (g) are (g) are (g) and (g) are (

would be expected to break covalent bonds formed by reaction of glutaraldehyde with integral membrane proteins. It is not even clear why glutaraldehyde fixation would affect the structure of the tight junction strand at all, unless it cross-links cytoplasmic28 or peripheral membrane proteins associated with the tight junction strands. (2) Tight junction strands form within minutes in the absence of protein synthesis and without any noticeable change in the density or pattern of distribution of the intramembrane particles2. However, punctate dimples and very short segments of tight junction strands are occasionally observed in plasma membranes of specimens rapidly frozen just as tight junction proliferation begins. We tentatively regard these dimples as early steps in tight junction formation because similar punctate dimples represent points of contact that become the sites of monolayer and bilayer rupture required for membrane fusion between artificial protein-free bilayers^{23,27}.

Transitions from planar bilayer to cylindrical micelles are also invoked in models of bilayer fusion 10,11,21,27. In these transi-

tions, the area of the polar side of the monolayer is thought to decrease while that of the hydrocarbon chain layer expands, so that the lipids pack into highly curved inverted cylindrical micelles with outward-facing hydrocarbon chains. A similar process could lead to tight junction formation; segregation and packing of lipids during the phase transition would account for the formation of the intramembrane cylinder. These changes might involve a transition of the planar lipid bilayer to a cylindrical micelle in an hexagonal II phase, similar to that invoked in models of membrane fusion, but here somehow stabilized in the form of pairs of offset, inverted cylindrical micelles segregated within an interbilayer fusion. Figure 2c illustrates in cross-section the proposed micellar organization of the lipids at the tight junction strand. Figure 2d shows how this model can be applied to the interpretation of a freeze-fracture image.

The presence of a continuous cylinder intercalated between two protoplasmic faces as seen in apical or basal views of tight junctions (Fig. 1e) requires that there be a continuous, linear

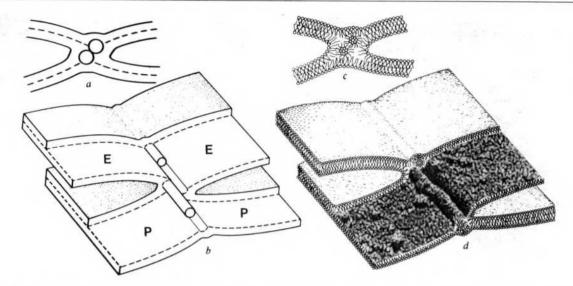

Fig. 2 a, Diagram of a cross-section of a tight junction strand illustrating the offset disposition of the pair of intramembrane cylinders. b, Diagram illustrating the paired offset cylinders at a tight junction strand and the different possible planes of fracture through such a junction. c, Proposed organization of the phospholipids at a tight junction strand. d, Diagram of phospholipids combined with freeze-fracture micrograph to show how fractures through lipid micelles could produce images characteristic of tight junctions,

interruption of the exoplasmic halves of the bilayer around an individual cell (Fig. 2b). However, the presence of inverted cylindrical micelles inside the membrane would also require continuity of the exoplasmic halves of bilayers of neighbouring cells across the tight junction strand (Fig. 2c). In fact, thin sections across tight junctions show points of partial membrane fusion, where only the exoplasmic leaflets of adjacent membranes have become continuous^{5,29,30}. Also, fluorescence quenching experiments show that lipid probes limited to the exoplasmic leaflets of cells joined by tight junctions are prevented from passing from their apical to their basal surface, while lipid probes that reach the protoplasmic leaflet can move freely around the cell circumference31. Thus the interpretation of tight junction structure presented here is consistent with their role as barriers that prevent diffusion between extracellular spaces and isolate apical and basal regions of the plasma membrane^{5,31}. It also shows how lipids and possibly other membrane components might flow from cell to cell within shared exoplasmic membrane leaflets.

Bryan Schroeder performed the photographic work, Nicholas Christakis helped with laboratory work, Trudy Nicholson prepared Fig. 2, and Sandra Cotter typed and provided editorial assistance. We especially thank Peter Rand and Richard Ornberg for valuable discussions during preparation of the manuscript.

The structure of a pseudo intercalated complex between actinomycin and the DNA binding sequence d(GpC)

Fusao Takusagawa*, Michael Dabrow*, Stephen Neidle† & Helen M. Berman*

Actinomycin D (AMD) is used clinically to treat tumours such as Wilms' tumour and gestational choriocarcinoma. It inhibits transcription in most cellular systems3,4, and binds to DNA, not to RNA3-5, with a preference for guanine6. The study of the crystal structure of a 2:1 complex between deoxyguanosine and AMD demonstrated both stacking and hydrogen-bonding interactions between the drug and the guanine ring7. Solution studies8,9 have indicated that the drug binds preferentially to guanine-pyrimidine sequences, such as d(GpC), and that an intercalated complex forms with both DNA¹⁰ and DNA fragments¹¹. External binding¹² and intercalation^{10,13} models for the structure of the complex between AMD and DNA have been proposed, but until now no crystal strucutre of a complex between AMD and an oligonucleotide has been reported. As the smallest unit of DNA with the potential for forming an intercalated duplex is a self-complementary deoxydinucleoside monophosphate, we undertook the crystallographic analysis of the 2:1 complex between deoxyguanylyl-3', 5'-deoxycytidine, d(GpC), and AMD. The complex is found to form an unusual pseudo-intercalated structure.

Crystals of the complex were produced from aqueous solution with 3 mM d(GpC) and 1 mM AMD, using a vapour diffusion method. The red-orange crystals, some of which were thin hexagonal plates and others tetragonal rods, appeared after about 1 month. Spectroscopic analysis of dissolved crystals revealed a 2:1 ratio of d(GpC) to AMD. X-ray diffraction studies showed the hexagonal crystals to be isomorphous with the tetragonal ones and indicated a trigonal crystal system with cell dimensions a = b = 16.577(3) Å and c = 56.200(8) Å. The intensities were measured at 0 °C on a diffractometer using 75uK α radiation and a co-axial gas flow cooling system. Reflection intensities were measured in one octant $(h\bar{k}l)$ of reciprocal space with $2\theta \le 62^{\circ}$ (1.5 Å resolution), using a $\theta/2\theta$ scan technique. A total of 3,706 reflections were collected and their intensities were corrected for absorption¹⁴ and decay. The data were then averaged assuming point group 3m symmetry yielding 1,668 independent reflections. A systematic absence is observed in the 00l zone with $l = 3n \pm 1$, thus the four possible space groups are P3₁21, P3₁12, P3₂21 and P3₂12. For the 1.5 Å resolution data the percentage of observed reflections on $1\sigma(\text{Fo}^2)$ and $2\sigma(\text{Fo}^2)$ levels are 74% and 58% respectively. From the observed crystal density (1.36 g cm⁻³) and unit cell volume (13,374.5 Å³), three complexes (molecular weight 2,366) and about 215 water molecules were predicted to be in the unit cell. All possible space groups require that the complex use the crystallographic 2-fold axis. AMD itself does not possesss exact 2-fold symmetry, hence its amino and quinoid groups are statistically disordered.

The structure was determined by inspection of the Patterson map and computerized electron density fitting procedures¹⁵. Refinement procedures resolved the space group ambiguities. After several cycles of constrained-restrained least-squares refinement, water molecules began to appear in the difference Fourier maps and were added to the structure; most of them are disordered. The current R-factor is 19% for all data and 15% for 2σ data. The fractional coordinates of the complex have been deposited in the Cambridge data file.

The principal and surprising feature of the crystal structure (Figs 1a and 2a, b) is that it does not contain the intercalated duplex structure (Fig. 1b) proposed, for example, by Sobell and Jain¹³ on the basis of the crystal structure of the 2:1 complex between deoxyguanosine and AMD⁷. Instead the d(GpC) molecule is in the opened-out conformation with the phosphodiester torsion angles in the g⁺g⁺ range rather than the g⁻g⁻ range found in self-complementary duplexes 16-21; thus its conformation is similar to that displayed by ApU²² complexed with 9-amino acridine. The dinucleoside phosphate molecules are connected to each other via Watson-Crick base pairs, to form infinite chains, with each hydrogen-bonded d(GpC) chain making a right-handed spiral around the crystallographic screw axis. Each AMD molecule, whose structure is very similar to the one complexed with deoxyguanosine alone⁷, is located between these chains with its phenoxazone ring sandwiched between Watson-Crick base pairs from these different chains. The complex is thus pseudo-intercalated. In the AMD binding site, the phenoxazone ring stacks predominantly with both guanine rings and has very little overlap with the cytosines (Fig. 3). The guanine residues also interact with the cyclic peptide rings of AMD via hydrogen bonds between their amino group N-2 and ring nitrogen N-3 and the carbonyl oxygen and amide group of threonine residues respectively (Fig. 2). The same intercomplex hydrogen bonds were found in the 2:1 complex between deoxyguanosine and AMD⁷

It is not yet clear why the d(GpC) does not form a duplex in the crystal because there is no chemical feature, such as base protonation, that would preclude such a structure. However, the rigid requirements for drug binding are incompatible with the conventional intercalated structures²¹, because the base pairs must form an unusual stacking pattern with the phenoxazone ring (Fig. 3) for the guanine to be positioned correctly for hydrogen bonding with the threonine (Fig. 2). Although we were able to build a stereochemically acceptable

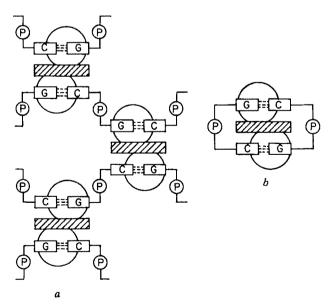

intercalated model, the conformation of the dinucleoside phosphate backbone is unusual. This may explain in part the unusually large ³¹P-NMR downfield shifts observed in complexes between AMD and small oligomers^{23–25}. These results also support the view that intercalation alone has a sequence preference at the dimer level. Although the crystal structures of both GpC¹⁶ and ApU¹⁷ show double-helical conformations, when ApU is complexed with 9-amino-acridine²² and when the deoxy form of GpC is complexed with AMD, duplexes do not form in the crystal. To date, without exception, all the known crystal structures of duplex-intercalated drug complexes have pyrimidine-3', 5'-purine sequences²¹ including the daunomycin hexamer complex²⁶. Furthermore, potential energy calculations for dinucleoside phosphates²⁷ indicate that standard intercalation geometries appear to favour that sequence.

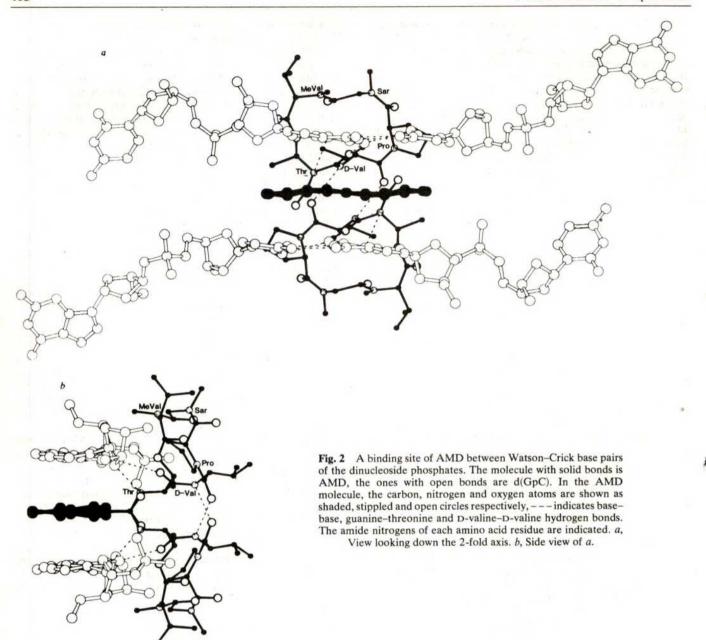

tion geometries appear to favour that sequence.

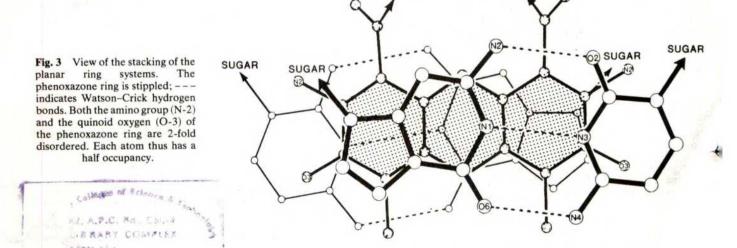

This analysis supports the proposals 10,12,13 that two 2-amino purines, such as guanine, are important, if not always essential²⁸ for the binding of AMD to DNA. The AMD molecule hydrogen-bonds only to guanine and not to cytosine, and it is the guanine base that is predominantly stacked with the phenoxazone ring (Fig. 3). Furthermore, only one of four possible orientations of the Watson-Crick G · C base pair allows hydrogen bonds to form between the cyclic peptide and the amino group N-2 and ring ntirogen N3 of the guanine ring. From considerations of base-drug interactions alone it would be predicted that AMD could bind to duplex d(GpC) but not to duplex d(CpG) because only the former sequence meets the hydrogen-bonding requirements. On the other hand, d(CpG) in an open conformation can complex with AMD⁸. In this structure the cytosine serves only as an accessory in anchoring the guanine in an optimal position for binding to AMD.

An examination of this structure shows why AMD cannot bind to RNA. If the deoxyribose of the guanosine (and not the cytidine) were changed to a ribose sugar, the O-2' hydroxyl group would have unusually short contacts with the amino group N-2 of the phenoxazone ring. This would also be the case in an intercalated model¹³ in which the distance between C-2' and the amino nitrogen N-2 is already quite short; it would thus be clearly impossible to replace the guanosine deoxyribose by ribose.

Using the results of this analysis it is possible to build a model of DNA in which guanine and cytosine residues from adjacent helices are involved in hydrogen-bonded cross-linking that is

eal Yechnology +o 集 Respect Tootheelegy PEPTIDE

PEPTIDE

stabilized by AMD. Further studies are necessary to determine whether this type of structure can exist in oligo- or polynucleotide-AMD complexes and if such structures are biologically significant. In recent studies²⁹ of semisynthetic AMD derivatives where both amino N-2 and C-7 sites of the phenoxazone ring were modified by substituting bulky groups for hydrogen atoms, the analogues were found to be effective antitumour agents, to inhibit DNA and RNA synthesis and to bind to DNA. In these cases it is difficult to envision a sterically feasible intercalation model that also incorporates the peptide-base hydrogen bonds; however, it is easy to fit these semisynthetic AMDs into a cross-linked structure, suggesting an alternative explanation for a part of AMD's chemotherapeutic action. Cross-linking may also provide an explanation for some of the unusual ³¹P-NMR results observed with short DNA oligomers in solution²³⁻²⁵. Clearly not all the activities of AMD need be explained by classical intercalation.

A gene deletion ending at the midpoint of a repetitive DNA sequence in one form of hereditary persistence of fetal haemoglobin

P. Jagadeeswaran, D. Tuan*, B. G. Forget & S. M. Weissman

Departments of Human Genetics and Medicine, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA

The form of hereditary persistence of fetal haemoglobin (HPFH) that commonly occurs in black populations is an inherited disorder of haemoglobin synthesis characterized by a uniformly high level of fetal haemoglobin (HbF) synthesis in all the erythroid cells of affected adult individuals^{1,2}. The precise molecular basis of the HPFH phenotype remains unknown, but is of great interest because of the knowledge that could be gained, through its understanding, of the mechanisms that regulate the expression of globin genes during development. The most common form of HPFH in black populations is associated with an extensive deletion that includes the normal adult (δ and β) globin genes and adjacent flanking DNA³⁻⁸. To investigate this disorder in more detail, we have cloned the DNA encompassing the region of the gene deletion in a case of HPFH and have determined the nucleotide sequence across the 5' end point of the deletion within the non- α -globin gene complex. We report here that this end point maps at the midpoint of a member of the 'AluI' family of repetitive sequences located approximately 4 kilobases (kb) to the 5' side of the δ -globin gene. Such repetitive sequences may be 'hot spots' of recombination, and are possibly involved in regulating gene expression.

The isolation and characterization of the HPFH DNA clone will be described elsewhere (D.T., S.M.W. and B.G.F., in preparation). The restriction endonuclease map of the human

non- α -globin gene cluster in the region of the HPFH deletion end point that was cloned is shown in Fig. 1. The deletion end point occurs \sim 4 kb 5' of the δ -globin gene. The normal DNA flanking the 5' extremity of δ -globin gene that was cloned by Lawn et al.9 was subjected to nucleotide sequence analysis in our laboratory and was shown to contain the following noteworthy structural features (see also Fig. 1); (1) an inverted pair of 300 nucleotide-long repetitive DNA sequences of the 'AluI' family (refs 10-14) separated by ~700 bp of intergenic DNA and located \sim 4 kb from the 5' end of the δ -globin gene, and (2) a remarkable segment of DNA located ~1 kb from the 5' end of the δ -globin gene that contains (with one exception) over 200 successive pyrimidine nucleotides on one strand of the DNA12

Figure 2 compares the nucleotide sequences of normal and HPFH DNA starting at the 5' EcoRI site of the 3.1-kb EcoRI DNA fragment adjacent and 5' to the 2.25-kb EcoRI DNA fragment bearing the 5' end of the δ -globin gene (Fig. 1; refs 9, 13). The two sequences show perfect homology with only two base differences as far as residue 370 from the 5' EcoRI site (Figure 2); beyond this point there is only very limited, patchy homology between the two DNA sequences, Figure 2 shows that the normal sequence retained in the HPFH patient extends half-way through the upstream (5') member of the pair of inverted Alu family DNA sequences located 5' to the δ globin gene. Thus the deletion in HPFH removes >3,000 nucleotides of the DNA flanking the 5' end of the δ -globin gene, including one and a half members of the pair of inverted Alu family repetitive DNA sequences and an extensive polypyrimidine stretch, then extends through the δ - and β -globin genes for an unknown distance 3' of the β -globin gene. The 3' Alu family DNA sequence that is totally deleted in this case of HPFH is known to be transcribed in vitro by RNA polymerase III to yield an RNA molecule 490 nucleotides long (although it is unknown whether such transcription occurs in vivo), whereas the 5' Alu sequence that is half deleted is not transcribed in vitro 10,11,14; the transcriptional orientation of this 3' Alu sequence is the same as that of the δ -globin gene.

It has been postulated 15 that the inter-γ-δ gene DNA may contain control elements, the deletion of which is responsible for the HPFH phenotype. Potential candidates for such regula-

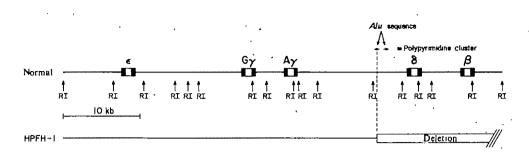

Fig. 1 Schematic representation of human non-α-globin gene cluster, showing the location of the deletion involved in the studied case of hereditary persistence of fetal haemoglobin (HPFH-1) Vertical arrows indicate EcoRI restriction endonuclease cleavage sites. Solid boxes show coding regions, and open boxes the large intervening sequences of the globin genes. 'Alu sequence' indicates the two copies of moderately repetitive DNA sequences of the AluI family located 5' to the δ globin gene.

tory sequences are the Alu repetitive DNA sequences and/or the polypyrimidine tract described above, although the specific molecular mechanisms by which deletion of these DNA elements could mediate failure of postnatal repression of the fetal γ -globin genes only on the cis chromosome bearing the deletion, are unknown and remain the subject of speculation. On the other hand, the coincidence of the deletion end point with an Alu family repetitive DNA sequence may indicate that Alu sequences, because of their number, chromosomal distribution and sequence homology, can serve as 'hot spots' for intrachromosomal recombinational events that lead to DNA deletions. Such recombinational events would be expected to occur between two homologous Alu sequences and result in a fusion product containing portions of the two Alu sequences involved in the nonhomologous cross-over. In HPFH, however, only half of an Alu sequence persists as opposed to a full-length fused Alu sequence. One must therefore implicate other mechanisms for the loss of the other half of the expected fused Alu sequence. It is also possible that a cross-over occurred between two relatively nonhomologous DNA sequences on the

Fig. 2 Comparison of normal inter- γ - δ gene DNA sequence (upper line) with that of the DNA across the 5' end point of the deletion in HPFH (lower line). Asterisks show positions at which an identical nucleotide is found in both sequences. The short arrows overlying the sequence indicate the direct repeats that flank the extremities of the normal AluI DNA sequence and the solid line overlies the entire length of the normal AluI repetitive DNA sequence.

chromosome bearing the non α -globin genes. Only limited spotty homology has been previously noted for DNA sequences involved in various recombination events between simian virus 40 (SV40) viral DNA and host genomic DNA¹⁶

Two other cases involving presumed recombination within AluI repetitive DNA sequences are known; one where a portion of an AluI repetitive DNA sequence from the genomic DNA of infected monkey kidney cells has been incorporated into SV40 (ref. 17) and another in which an α -globin gene has been partially deleted and fused to a repetitive DNA sequence of the AluI family¹⁸. In both cases, the recombinational events occurred internally within the AluI repetitive DNA sequences rather than at their boundary. It is not clear whether such occurrences are coincidental because of the high frequency of the AluI family sequences in the total genome, or whether there is some special propensity for nonhomologous recombination to occur within DNA stretches containing AluI repetitive sequences. Note, in this regard, that a number of deletions have been found in a yeast tRNA gene cluster that is flanked by short repetitive DNA sequences 19

Finally, because there is another deletion producing HPFH in blacks that has a different 5' end point extending across the same region of DNA^{7,8}, it seems unlikely that the HPFH phenotype in these cases is due to a second undetected mutation remote from the region of the deletion. It is possible, however, that the size of the deletion itself, the loss of downstream sequences, or the nature of the DNA brought as a result of the deletion into the vicinity of the fetal γ -globin genes is responsible in some way for the continuing expression of γ -globin genes in HPFH. Characterization of the DNA at the 3' end point of these HPFH deletions is in progress and may elucidate further the mechanisms responsible for the HPFH phenotype.

BOOK REVIEWS

The central problem in human evolution

C. Owen Lovejoy

DIET has always figured prominently in studies of the adaptation and evolution of mammals. This is to be expected, as most of the fossil record is composed of teeth and jaws, and feeding adaptations, aside from reproduction, are probably the most critical selective force in mammalian evolution. Moreover, the two-million-year archaeological record is made up of food remains and the tools used to obtain and process them. Superimpose upon this background such current debates as human sex roles, the quantitative analysis of archaeological sites and the forces at play in the origin of hominids, and the result is a cauldron of intense debate about facts and theories of almost every phase of human evolution.

The fourteen chapters comprising Omnivorous Primates are predominantly devoted directly to the problem of reconstructing the role of diet in human evolution. There are essentially four ways by which this can be done: by study of the archaeological record (three chapters); by study of the dietary habits of non-human primates (four chapters); by study of the dietary habits of contemporary huntergatherers (four chapters); and by direct study of the dental remains of hominids. Given the great advances and significant work which has been conducted in the past few years in the latter area, it is surprising that this volume contains no contributions dealing directly with these methods. One additional chapter which was not classified above deserves special mention. Alan Mann presents a thorough general essay on diet in the Plio-Pleistocene hominids using all of the four categories of data. He details dietary requirements of primates, reviews the historical development of various theories of feeding strategy in early human evolution (for example hunting, seedeating, gathering), looks at the direct evidence available in cranial morphology, and summarizes with a discussion of models of early hominid dietary exploitation, concluding that the best model is one which posits a diet of marked diversity, significantly enhanced by the use of primitive tools with which to exploit underground food sources. It is of interest that the diet posited by Mann (as he himself points out) is quite similar to that found in Gombe chimpanzees (minus the underground rhizomes).

In his own paper Teleki provides a detailed account of this diet, including data on activity rhythms and feeding budgets. Most of his contribution, however, is

Omnivorous Primates: Gathering and Hunting in Human Evolution. Edited by Robert S. O. Harding and Geza Teleki. Pp.673. ISBN 0-231-04024-5. (Columbia University Press: 1981.) \$52, £28.60. Woman The Gatherer. Edited by Frances Dahlberg. Pp.250. ISBN 0-300-02572-6. (Yale University Press: 1981.) \$15, £10.50.

devoted to a factual description of chimpanzee meat consumption, in which he notes many aspects which may bear significantly on early human behaviour (for example evidence of "cooperative behaviour", food sharing and a sexual division of activity, to wit: "pursuit, capture and consumption of animals are primarily male activities, while collection of insects . . . is primarily a female activity"). In fact he concludes that "chimpanzees are ecologically, behaviourally, socially, and psychologically best suited to serve as a model for reconstructing human origins".

There are a number of similarities between Teleki's chimpanzees and the hunting behaviour in Gilgil baboons which is carefully presented by Shirley Strum (including cooperation, sexual differences in hunting behaviour and food sharing), but her contribution is of particular note for a different reason. Her continuous observation of a single group for over seven years has allowed her to chronicle significant changes in behaviour in response to ecological, demographic and social fluctuations. Her report strikes home the too-often forgotten fact that our knowledge of primate behaviour is based on but a few short-term studies of single groups which must be extended to millions of years of primate evolution.

As a whole, the volume is well-edited and produced, and will be valuable not only to those interested in human evolution and primate behaviour, but archaeological methods and ethnography as well. All of the contributions are competent and informative. Harding presents a general review of primate diet, and Hayden a similar world-wide review of diet in modern hunter-gatherers. Gould's review of food-acquisition and sharing behaviour in Australia and north-west California should prove particularly useful to prehistorians who must deal with the problem of the interpretation of food remains from archaeological sites. There is an informative up-date on the age-old

question of Pleistocene extinctions by David Webster.

In contrast to Omnivorous Primates, Woman the Gatherer contains virtually no contributions to the current debate. The title is an obvious word-play with respect to an earlier volume which has had farreaching influence in modern anthropology, Lee and Devore's Man the Hunter. That volume was, in fact, more responsible than any other (despite some of its contributions and title to the contrary) in fully establishing the crucial role of women as gatherers and contributors to the success and function of pre-urban human societies. This new book, its title again to the contrary, contains little to amplify this now generally recognized fact. The article by McGrew, summarizing observations from a variety of field studies, is a thorough and highly competent account of (primarily female) chimpanzee behaviour, and in this regard is useful and informative. The model presented at the end of the article, however, falls short of actually being a model, but rather stands only as a brief account of a theoretical chimpanzeelike-hominoid to hominid transition without attention to selective mechanisms - the critical element in any successful model. A contribution by Zihlman, on the role of female gathering in human evolution, while again a useful account, suffers from the same deficiency.

Other papers in this volume, although of general interest, fall short of having a significant bearing on the actual role of females in long-term human evolution. Papers on hunting behaviour among Agta women, Mbuti womanhood, and the collection and preparation of food by Chipewayan women are useful contributions, but fall short of being directly applicable to the problems of human evolution. A long and involved paper by Catherine Berndt presents a rather cryptic account of the misuse of data obtained from observations of the Australian aborigines. Readers will suffer from her inherent assumption that they are intimately familiar with this arena of

These two volumes, taken as a pair, raise certain rather interesting questions and paradoxes about viewpoints frequently adopted in the study of human evolution. The most disturbing of these is the failure to recognize the relatively enormous behavioural "gulf" between the australopithecines and modern man. Based upon what we know of the morphology of these

two taxa, that "gulf" must be approximately similar in magnitude to present differences between chimpanzees and hunter-gatherers. Primatologists (and one sees it frequently in these two volumes) often adopt an attitude that human behaviour is little more than slightly elaborated chimpanzee (or other primate) behaviour; ethnographers can, to the contrary, take the view that australopithecines were hunter-gatherers with robust faces and walnut-sized brains. Both groups would do well to study with great care the contributions to Omnivorous Primates by Freeman and Klein. These authors carefully document and chronicle the dramatic and progressive development of dietary shifts which took place in the middle and late Pleistocene in the Iberian Peninsula and the circumcoastal region of South Africa. While the question of the actual origin of hominids is critical and intriguing, the transformation of a

chimpanzee-like bipedal hominid into a cognitive, social and technological animal took place during the middle Pleistocene, a period for which no living analogues exist. There has been an overall assumption that Homo erectus was simply an intermediate between australopithecine and human being, but the archaeological evidence does much to contradict such an assumption. All living societies, no matter how "primitive", post-date the dramatic advances in upper Palaeolithic technology and the unquestionably equally dramatic alterations in social and subsistence behaviour which accompanied them. It is clear that we will lack a complete understanding of the process of human evolution until this vast yet crucial middle period is given the detailed attention it most sorely deserves. П

An atomy of the Origin of Species

L. Beverly Halstead

A Concordance to Darwin's Origin of Species, 1st Edn. Edited by Paul H. Barrett, Donald J. Weinshank and Timothy T. Gottleber. Pp.834. ISBN 0-8014-1319-2. (Cornell University Press: 1982.) \$38.50, £27.

How appropriate it is, in the year marking one hundred years since Darwin's death, that his best-known book should join that other great British institution the "Complete Works of William Shakespeare" to say nothing of the Bible. All students of evolution and Charles Darwin will be indebted to Cornell University Press for their concordance to the *Origin of Species*, first edition.

This concordance is perhaps the supreme monument to what a computer can do with a book and also to what university teachers can accomplish with the help of undergraduates — who, in this case, patiently

typed 834 pages of text at 86 lines to a page. Unlike the concordance to the Bible, where the full context is listed under each entry and one can obtain all the useful quotations without ever having to open the Bible itself, with the present work such an approach is not possible. Each entry listed is printed in the centre of the page with sufficient of the adjacent words to fill a single line of print, no more and no less. This means that the entries rarely make up a complete sentence, and if they are at the end of a sentence the following quotation may well be entirely irrelevant to the entry. Reference to the first edition itself, or rather a facsimile, is thus essential. The publishers of the facsimile, Harvard University Press, should be duly grateful.

Every student of evolution will wish to possess this concordance, but it must be stressed that for all its thoroughness the three editors found it necessary to suppress certain words, for example "the" 10,144 times, "of" 7265, "in" 3904, "to" 3563; "you" which occurred three times was also suppressed.

To my amazement, Darwin did not include a single mention of the aardvark. and zoological appeared only twice with single entries for zoologist and zoologists. Geological, geologists and geology together merited 128 entries, thus emphasizing the relative importance of these two disciplines in Darwin's eyes. Even the creationists are well catered for in that they can readily list the number of qualifying prepositions, nouns, adverbs and adjectives used. Insights into Darwin's relationship with other scientists of the period can also be extracted from this work. Charles Lyell is mentioned 27 times in such phrases as "Lyell's noble views" "Lyell's grand work", "Lyell's profound remark" "Lyell's manual will bring home the truth". Huxley rates a mere 4 mentions. Murchison 4, Adam Sedgwick 2, whereas Owen and Agassiz with 18 and 10 respectively do much better.

The use of certain words must surely be significant: for example Darwin uses the first person singular some 999 times. And although Darwin's theory arose primarily from his circumnavigation of the world aboard the H.M.S. Beagle, this vessel is mentioned but twice, firstly in the opening sentence of the book: "When on board H.M.S. Beagle, as naturalist, I was much struck by certai" (there the entry ends). The other word that is remarkable for the circumspection with which it was used by Darwin is the last word in the book: "and most wonderful have been, and are being, evolved".

There is one further criticism that can be levelled at this volume: at no place is it possible to discover the full title of Darwin's book. Once again it is necessary to refer to the Harvard facsimile: On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life.

Ion transport for enthusiasts

N. Michael Green

The Sarcoplasmic Reticulum: Transport and Energy Transduction. By Leopoldo de Meis. Pp.163. ISBN 0-471-05025-3. (Wiley:1981.) £29.25, \$52.50.

Over the past 12 years the sarcoplasmic reticulum has become increasingly popular as a model system for the study of transport of ions across membranes. Physiology, electron microscopy, techniques of membrane reconstitution, lipid chemistry, protein chemistry and enzyme kinetics have all contributed to make this one of the best known of subcellular organelles.

This short monograph is concerned with the author's own field of kinetic studies on isolated vesicles of sarcoplasmic reticulum, to which he has made significant contributions. After two concise and informative introductory chapters, Dr de Meis restricts himself to this area. By concentrating his attention in this way he is able to present a variety of steady state and transient state kinetic experiments which have led to the generally accepted minimal cycle of at least eight reversible reactions that are responsible for Ca++ translocation. Since Ca++, Mg++ and ATP each enter the cycle more than once, it has required considerable experimental ingenuity to provide even a qualitative description of the reaction sequence. The chief merit of the book is that it presents crucial experiments from laboratories in well-illustrated detail, providing a valuable perspective for anyone trying to find his way through the 300 or more papers quoted. Mastery of the evidence presented will bring the reader to the end of 1980 and to a good position from which to cope with the arguments of 1981 and beyond, for the story is by no means over.

The author says very little on several important questions on which the evidence is conflicting and it would have been helpful to have had these problems more clearly delineated. They include the related questions of a monomeric versus a dimeric functional unit and of the number of Ca⁺⁺ and ATP binding sites per peptide chain. The questions of co-transport or countertransport of other ions and of the possible electrogenic nature of the pump are barely considered, while excitation-contraction coupling and Ca⁺⁺ release mechanisms are explicitly excluded.

The final chapter on the role of water in the active site of the ATPase is rather speculative, being based in part on the effects on the stability of the acyl phosphate of dimethylsulphoxide, which is assumed to be a hydrophobic solvent; this assumption is hardly warranted by its very high dielectric constant. The remarkable changes in reactivity undergone by the acyl phosphate intermediate during the catalytic cycle are more likely to be a

consequence of local electronic influences than of a general change in accessibility of the catalytic site to water.

These are minor reservations, however, and do not seriously detract from the value of this book to all those interested in an analytical approach to ion transport.

N. Michael Green is in the Division of Biochemistry, National Institute for Medical Research, Mill Hill, London.

Intention in mind

Richard Gregory

Mind Design: Philosophy, Psychology, Artificial Intelligence. Edited by John Haugeland. Pp.368. Hbk ISBN 0-226-08110-5; pbk ISBN 0-226-58052-1. (MIT Press: 1981.) Hbk \$21.50, £13.50; pbk \$10, £6.20. Minds and Mechanisms: Philosophical Psychology and Computational Models. By Margaret A. Boden. Pp.311. ISBN 0-855-27064-0. (Harvester/Cornell University Press: 1981.) £20, \$29.50.

Mind Design, a collection of 12 papers by computer scientists and philosophers of AI, was conceived by its editor, John Haugeland, as a sequel to A.R. Anderson's Minds and Machines which was published by Prentice-Hall in 1964. This new collection offers essays by Allen Newell and Herbert Simon; Zenon Pylyshyn; Marvin Minsky; Drew McDermott; Hubert Dreyfus; Hilary Putnam; Daniel Dennett; John Searle; Jerry Fodor; and Donald Davidson. There is also the particularly welcome essay, "Artificial Intelligence - A Personal View", by David Marr, whose recent death while at the height of his genius was a tragic blow for computer vision as well as for his many friends. The editor himself contributes an insightful Introduction, "Semantic Engines", and a rather less interesting essay on cognitivism.

In his Introduction, Haugeland asks how the psychology of thought can be properly scientific when thoughts cannot be observed; though the problem is not like that of galaxies or electrons, that they are too far away or too small. Referring to the "marvellously rich analogy with computers", and especially to a chessplaying machine, which "would be awkward to describe [in] its functioning by assigning geometrical shapes and locations to the internal program routines, yet has no immaterial soul" the crucial question is raised: how far is the human chess player like the machine that may beat him in intellectual combat?

A central issue throughout the book is

The Changing Climate:

Responses of the Natural Flora and Fauna

Michael J. Ford.

Nature Conservancy Council

Choosing a wide range of natural examples, Dr Ford considers the different levels at which climatic effects operate on individual species and communities. Although the magnitude of climatic change this century is quite small, the author argues that its effect on natural flora and fauna may be disproportionate. Man's destruction of natural habitats includes climatically favourable areas providing refuge in times of climatic stress. If these disappear, certain species may be endangered.

Circle No.04 on Reader Enquiry Card.

intention; here the American philosopher Dan Dennett has interesting things to say, also using the chess-playing computer example. He points out that even the designer cannot predict the next move of the machine from its design. He can only do so by considering rational and good moves of the game, which implies that the machine "chooses" rational and good moves. So, one is viewing machines such as these in intentional terms. Dennett, however, is careful to say that we may be right to attribute a lot more to human beings than this rather limited kind of intention, though he is not sure what this extra is.

Hubert Dreyfus is the respected devil's advocate of AI, whose book What Computers Can't Do (Harper & Row, 1972) provided, to the credit of all, reasoned criticisms that have been discussed with reason and not merely dismissed by the high priests of AI. Here Dreyfus adapts to the new developments of computer systems, starting with the universally acknowledged achievement of Winograd's natural language understanding program SHRDLU of 1972, which worked in a simplified micro-world, which was not much like our reality. Dreyfus objects to a common AI assumption, that such manageable microworlds can be generalized to the real world of physics and people. He suggests that proponents of AI are misled by the success of test-tube procedures in the natural sciences into thinking that these microworlds are even relevant; because although the test-tube worlds of physics obey physical laws, the computer micro-worlds may obey only their own laws. I suppose the answer is that "mental" laws are not physical laws anyway, so the whole exercise is outside physics; but it may still be science. Perhaps only physicists will strongly object to this conclusion.

Marvin Minsky invokes the notion of structures of knowledge — "frames" — to match common situations and to be adapted to the special features of situations. He attributes human intelligence to the individual's ability to select frames appropriately and rapidly. Selected knowledge frames are adapted to match the details of particular situations as they are encountered. This bears a resemblance to Bartlett's "Schemas" for locking together and giving significance to perceptions and memories. It is also related to David Marr's "Primal Sketch", his

AI at MIT

At the end of April, MIT Press will publish a two-volume paperback edition of Artificial Intelligence: An MIT Perspective edited by Patrick Henry Winston and Richard Henry Brown. The original hardback edition was reviewed in Nature 282, 540; 1979. Price of the paperback version is \$12.50, £8.75 per volume; hardback is available at \$25, £17.50 per volume.

initial descriptive stage of visual processing.

Several of the authors here express doubts on the scientific status of AI and its claims and results. For Marr,

a result in AI consists of the isolation of a particular information-processing problem, the formulation of a computational theory for it, the construction of an algorithm that implements it, and a practical demonstration that the algorithm is successful.

He points out, though, that there may be nice and neat successful solutions (which may not be found) and also messy solutions which may be as successful. Given the aesthetics of science, one may guess that AI will be accepted as properly scientific only if its solutions are both successful and elegant, whatever be the case for our own brain's functions — even when we are thinking about the challenging intellectual issues presented in these illuminating essays on artificial intelligence.

Margaret Boden's Minds and Mechanisms is a collection of her own papers on the philosophy of AI. Her concern with the concept of intention goes back to her first book, Purposive Explanation in

Psychology (Harvard University Press, 1972), and is also a theme of her widely acknowledged text, Artificial Intelligence and Natural Man (Harvester, 1977). Intention appears to be basic to any language system, and Professor Boden was largely responsible for pointing this out. Her strength lies in combining a deep knowledge of cognitive psychology, and what AI programs can and cannot at present do, with a background in both natural science and philosophy. The result is an authoritative book, though inevitably there is unevenness and some redundancy as the papers were written separately and for somewhat different audiences. Some of them take us more deeply into the issues of her previous books, and the technical detail presented here justifies careful reading for appreciating the fascination of mind struggling to be transmigrated into manmade machines that surprise and puzzle

F.A. Bovey

Molecular Motion in High Polymers. By R.T. Bailey, Alastair M. North and Richard A. Pethrick. Pp.415. ISBN 0-19-851333-X. (Clarendon/Oxford University Press: 1981.) £42.50, \$69.

As they state in their preface, in Molecular Motion in High Polymers the authors have essentially produced two books under one cover. Part A is primarily theoretical in nature and, after a general introduction, deals with normal vibrations and inelastic light scattering, various "hydrodynamic" models of chain motion and statistical theories of polymer molecular motion. The level of mathematical treatment is moderately high, and readers not comfortable with vector and tensor notation and matrix algebra will find themselves somewhat at sea.

Part B is described as a phenomenological treatment. It is more descriptive and the mathematical background is less prominent, although not at an elementary level. Most readers should be able to absorb this section with profit without necessarily resorting to Part A. Dielectric properties, photoluminescence, viscoelastic relaxation, ultrasonic relaxation, nuclear magnetic and electron spin resonance, spectroscopic and scattering phenomena, neutron scattering and diffusion are all well described.

My reservations about the book mainly concern the completeness of the treatment. More specifically, the literature citations

have a dated appearance. It should be possible to reference work within at most two years of the publication date, and in fact there is a reference to a 1980 paper by one of the authors. However, in general there are few references to papers later than 1975. This may be acceptable in an introductory textbook, but not in a scholarly treatise such as this. I was especially sensitive to this point in the chapter on nuclear magnetic and electron spin relaxation, my own field. Carbon-13 NMR, the area of greatest recent interest, is given rather short shrift. Although highresolution carbon-13 NMR of solids is described, the treatment is very compressed. Carbon-13 relaxation in solution, a major area, occupies less than a page, and most of the relevant literature is omitted. It should also be pointed out that the section on the inversion-recovery method for measuring T, has been mislabelled "Carr-Purcell Experiments", a quite different technique used for measuring T2.

This selective treatment means that readers cannot count on being brought to the forefront of the topics described. Despite this reservation, I found the discussion informative and valuable. The book is well written and can be read with pleasure.

F.A. Bovey is Head of the Polymer Chemistry Research Department, Bell Laboratories, Murray Hill, New Jersey.

ANNOUNCEMENTS

Awards

Professor George Weber (Laboratory for Experimental Oncology at Indiana University School of Medicine) has been elected for the 22nd Annual Clowes Award by the American Association for Cancer Research.

The Institution of Geologists has presented the Aberconway Medal to Dr D.J. Burdon.

Appointments

Dr David Mahoney is to head CSIRO's new Division of Tropical Animal Science.

Dr Robert E. Olson has been appointed associate dean for academic affairs at the University of Pittsburgh School of Medicine and also professor in the Departments of Biochemistry and Medicine.

James "Scotty" Miller has been named the first Director of Methods Development for the American Oil Chemists' Society.

Royal Society Fellows

At a meeting of the society on 18 March 1982, the following were elected Fellows of the Royal Society: Dr Ulrich Wolfgang Arndt (Medical Research Council Laboratory of Molecular Biology. Cambridge). Professor Rodney James Baxter (Theoretical Physics, Australian National University, Canberra); Professor Michael Victor Berry (Theoretical Physics, University of Bristol); Professor James Derek Birchall (ICI Ltd, Runcorn, Cheshire, and visiting professor of Materials Science, University of Surrey); Professor Anthony David Bradshaw (Botany, University of Liverpool); Dr Daniel McGillivray Brown (Organic Chemistry, University of Cambridge); Dr Lawrence Michael Brown (Physics, University of Cambridge); Professor Bryan Campbell Clarke (Genetics, University of Nottingham); Professor William Maxwell Cowan (Anatomy, Salk Institute for Biological Studies, San Diego, USA); Professor Alan William Cuthbert (Pharmacology, University of Cambridge); Dr John Thomas Finch (Medical Research Council Laboratory of Molecular Biology. Cambridge); Professor Henry Edgar Hall (Physics, University of Manchester); Professor Michael Hart (Physics, King's College, University of London); Dr Eric John Hewitt (Plant Physiology and Biochemistry Section of Long Ashton Research Station, Bristol, and Plant Physiology and Biochemistry, University of Bristol); Professor Charles Antony Richard Hoare (Computation, University of Oxford); Professor Robert Francis Hudson (Organic Chemistry, University of Kent at Canterbury); Professor Kenneth Langstreth Johnson (Engineering, University of Cambridge); Professor William

Johnson (Mechanics, University of Cambridge); Professor Peter Julius Lachmann (Tumour Immunology, University of Cambridge and Medical Research Council Unit on Mechanisms in Tumour Immunity, Cambridge); Dr Ralph Lainson (Wellcome Parasitology Unit, Belém, Brazil): Dr Michael Francis Land (Biological Sciences, University of Sussex); Professor Peter John Lawrenson (Electrical and Electronic Engineering, University of Leeds); Professor William Russell Levick (Physiology, John Curtin School of Medical Research, Australian National University, Canberra): Professor Stephen Finney Mason (Chemistry, King's College, University of London); Dr Noreen Elizabeth Murray (Molecular Biology, University of Edinburgh); Sir Gustav Nossal (Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia, and Medical Biology, University of Melbourne); Professor Ronald Harry Ottewill (Colloid Science, University of Bristol); Dr William James Peacock (Division of Plant Industry, CSIRO, Canberra, Australia); Professor Philip James Edwin Peebles (Physics, Princeton University, USA); Peter Rainger (British Broadcasting Corporation, London); Professor Chintamani Nagesa Ramachandra Rao (Indian Institute of Science, Bangalore); Dr Lewis Edward John Roberts (Atomic Energy Research Establishment, Harwell, and Board of the United Kingdom Atomic Energy Authority); Professor George Stanley Rushbrooke (Theoretical Physics, University of Newcastle upon Tyne); Professor John George Sclater (Marine Geophysics, Massachusetts Institute of Technology, USA); Dr Graeme Bryce Segal (Mathematics, University of Oxford); Professor David Rostron Trentham (Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, USA); Professor John Stewart Turner (Geophysical Fluid Dynamics, Australian National University, Canberra); Professor Thomas Gaskell Tutin (Taxonomy, University of Leicester); Professor John Conrad Waterlow (Human Nutrition, London School of Hygiene and Tropical Medicine, University of London).

Meetings

16-18 May, Biomedical Applications of LCEC and Voltammetry, Indianapolis (LCEC Symposium, PO Box 2206, West Lafayette, Indianapolis 47906, USA).

17-18 May, Cancer, London (The Marie Curie Memorial Foundation, 124 Sloane St, London SW1, UK).

17-21 May, Applied Combustion Technology, Geneva (The Center for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands).

18-20 May, Roots at Work, Wantage (Dr R.S. Bruce, ARC Letcombe Laboratory, Wantage, Oxon, UK).

19 May, Landfall Leachate Symposium, Oxford (Mr L. Evans, Education and Training Centre, Harwell Laboratory, Didcot, Oxon, UK).

24-27 May, Ceramics Technology for the Non-Ceramist, Amsterdam (The Centre for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands).

24-26 May, Male Transmission of Adverse Reproductive Effects, Cincinnati (Marvin Legator, University of Texas, Galveston, Texas 77550, USA).

25-28 May, **Biological Basis of New Developments**, Minnesota (P. Rogers, 1060, Mayo Memorial Bldg, Box 196, 420 Delaware St, SE Minneapolis, Minnesota 55455, USA).

24-28 May, Applied Pump Technology, Amsterdam (The Center for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands).

24-28 May, CAgM Working Group on Weather and Animal Health, Geneva (Research and Applications Programme Dept, World Meteorological Organization, Geneva, Switzerland).

25 May, Chemistry which Imitates Biochemistry: Artificial Enzymes, London (Miss J. Holman, The Ciba Foundation, 41 Portland Place, London W1, UK).

2-4 June, International Chlorine Symposium, London (The Conference Secretariat, Society of Chemical Industry, 14/15 Belgrave Square, London SW1, UK).

2-4 June, Endocrine Lung in Health and Disease, Washington DC (P. J. Petrossian, GWUMC-Office of CME, 2300 K. St, N.W. Washington DC 20037, USA).

13-16 June, **Birth Defects Conference**, Alabama (March of Dimes, 1275 Mamaroneck Ave, White Plains, New York 10605, USA).

29-June-1 July, Crystallization Technology, Amsterdam (The Center for Professional Advancement, Postbus 19865, 1000 GW Amsterdam, The Netherlands).

20 June-3 July, The Application of Laser Light Scattering to the Study of Biological Motion, Maratea (Charles Barker Lyons Ltd, 30 Farringdon St, London EC4, UK). 21-25 June, Radioimmunoassay and Related Procedures in Medicine, Vienna (IAEA, Wagramerstrasse 5, PO Box 100, A-1400 Vienna, Austria).

21 June-3 July, Cancer Epidemiology, Jabonna (International Agency for Research on Cancer, 150 cours Albert Thomas, F-69372 Lyon Cedex 08, France). 30 June-2 July, Applications of Vibrational Spectroscopy, Southampton (Dr J. Evans, Dept of Chemistry, The University, Southampton, UK).

- 5-9 July, Mechanisms of Reactions in Solution, Canterbury (Dr J. F. Gibson, The Royal Society of Chemistry, Burlington House, London W1, UK).
- 8-9 July, Materials and Testing London (The Institute of Physics, 47 Belgrave Square, London SW1, UK).
- 12-14 July, Electronic Systems Effectiveness and Life Cycle Costing, Norwich (Charles Baker Lyons Ltd, 30 Farringdon St, London EC4, UK).
- 17-25 July, Microbiology, Kansas (Dr Fung, Call Hall, Kansas State University, Manhattan, Kansas 66506, USA).
- 19-23 July, Statistical Methods in Cancer Epidemiology, Lyon (International Agency for Research on Cancer, 150 cours Albert Thomas, 69372 Lyon Cedex 8, France).
- 19-23 July, Correlation Analysis in Organic Chemistry, Hull (Dr J. F. Gibson, The Royal Society of Chemistry, Burlington House, London W1, UK).
- 19-24 July, European Congress on Cell Biology, Paris (Ist European Congress on Cell Biology, 67, rue Maurice-Günsbourg, 94200 Ivry-sur Seine, France).
- 19-30 July, Air-Sea Exchange of Gases and Particles, Durham USA (Charles Barker Lyons Ltd, 30 Farringdon St, London EC4, UK).
- 27-29 July, Strategies for Coping with Critical Issues Related to Materials and Minerals, New Hampshire (FMS, 345 East 47th St, New York, New York 10017, USA). 26 July-6 August, Genetic Engineering in Eukaryotes, Pullman (Charles Barker Lyons Ltd, 30 Farringdon St, London FC4, UK).
- 31 July-6 August, Living with Industry, West Yorks, (The SISCON Summer School Secretary, Combined Studies in Science, University of Leeds, Leeds, UK). 1-11 August, 11th INQUA Congress, Moscow (Prof. Dr Marton Pecsi, Institute of Geography, Academy of Sciences, Budapest, Hungary).
- 2-5 August, Meeting of the American Society for Viriology, Ithaca (H. S. Ginsberg, Dept of Microbiology, College of Physicians and Surgeons of Columbia University, 701 West 168th St, New York, New York 10032, USA).
- 2-6 August, Applications of X-ray Analysis, Denver (Mrs M. Cain, Denver Research Institute, University of Denver, Colorado 80208, USA).
- 5-6 August, Computational Physics on the Distributed Array Processor, Glasgow (The Institute of Physics, 47 Belgrave Square, London SW1, UK)
- 8-13 August, 9th Congress of the International Primatological Society, Atlanta (Dr F. King, Yerkes Regional Primate Research Center, Emory University, Atlanta, Georgia 30322, USA). 9-13 August, Joint Meeting, Electron Microscopy Society and Microbeam Analysis Society, Washington DC (Prof. T.E. Mitchell, Dept of Metallurgy and Materials Science, Case Western Reserve University, Cleveland, Ohio 44106, USA).

- 15-17 August, Functional Properties of Cereal Carbohydrates, Winnipeg (Dr R.D. Hill, Plant Science, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2). 16-18 August, Potential Utility of NMR in Research and Clinical Applications, Boston (Dr M.R. Goldman, Internal Medicine, Massachusetts General Hospital,
- 18-22 August, SV40, New York (G. Kist, Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, New York 11724, USA).

Boston, Massachusetts 02114, USA).

- 15-19 August, Genetic Engineering of Plants, California (Tsune Kosuge, Dept of Plant Pathology, University of California, Davis, California 95616, USA).
- 16-29 August, New Developments and Methods in Membrane Research and Biological Energy Transduction, Spetsai (Prof., Dr K.W.A. Wirtz, State University of Utrecht, Laboratory of Biochemistry, NL-3508 TB, The Netherlands).
- 24-29 August, **Phage**, New York (G. Kist, Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, New York 11724, USA).
- 30 August-2 September, Planetary Rings, Toulouse (CNES, Dept des Affaires Universitaires, 18, ave Edouard-Belin, 31055 Toulouse Cedex, France).
- 31 August-5 September, **Herpesvirus**, New York (G. Kist, Cold Spring Harbor Laboratory, New York 11724, USA).
- 31 August-2 September, Very Large Baseline Interferometry Techniques, Toulouse (CNES, Dept des Affaires Universitaires, 18 ave Edouard-Belin, 31055 Toulouse Cedex, France).
- 1-3 September, Annual Symposium of the Uranium Institute, London (The Uranium Institute, 8th Floor, New Zealand House, Haymarket, London SW1, UK).
- 1-3 September, Environment and Safety Conference, Wembley (Labmate Ltd, Newgate Sandpit Lane, St Albans, Herts, UK).
- 1-4 September, Mutihormonal Cellular Regulations in Neuroendocrinology, Colmar (Ph. Philippe Richard, Laboratoire de Physiologie Générale, Université Louis Pasteur, 21 rue René Descartes, 67084, Strasbourg Cedex, France).
- 6-10 September, **BA '82**, Liverpool (W. McQuarrie, University of Liverpool, Senate House, Abercromby Square, PO Box 147, Liverpool, UK).
- 8-9 September, Vertebrate Palaentology, London (Geological Society, Burlington House, London W1, UK).
- 8-10 September, **Optics** '82, Edinburgh (Institute of Physics, 47 Belgrave Square, London SW1, UK).
- 8-15 September, International Cancer Congress, Seattle (Congress Operations Office, 4th and Blanchard Building, Suite 1800, Seattle, Washington 98121, USA).
- 8-10 September, Coagulation, Cancer and Inflammation, Virginia (Dr A. P. Ball, National Heart, Lung and Blood Institute,

- Federal Building, Bethesda, Maryland 20205, USA).
- 8-18 September, Principles and Methods in Receptor Binding, Urbino (Dr I. Ceserani, Institute of Pharmacology and Pharmacognosy, University of Milan, Via A. del Sarto, 21, 20129 Milan, Italy).
- 9-10 September, Volcanic Processes in Marginal Basins, Keele (Geological Society of London, Burlington House, London W1, UK).
- 12-16 September, Loss Prevention and Safety Promotion in the Process Industries, Harrogate (The Institution of Chemical Engineers, George E. Davis Building, 165-171 Railway Terrace, Rugby, UK).
- 13-15 September, Supercritical Fluids: Their Chemistry and Applications, Cambridge (Dr W.R. Ladner, National Coal Board, Stoke Orchard, Cheltenham, Gloucester, UK).
- 13-16 September, 1982 Meteoretical Society, St Louis (Prof. Ghislaine Crozaz, Washington University, Box 1105, St Louis, Missouri 63130, USA).
- 13-17 September, The Neutron and its Applications, Cambridge (The Institute of Physics, 47 Belgrave Square, London SW1, UK).
- 13-17 September, International Society for Photogrammetry and Remote Sensing, Toulouse (GDTA, 18 ave Edouard-Belin, 31055 Toulouse Cedex, France).
- 13-17 September, 12th Congress of the International Federation of Societies of Cosmetic Chemists, Paris (Societe francais de Cosmetologie, 44 rue du 22 Septembre, 92400 Courbevoie, France).
- 13-17 September, World Filtration Congress, Philadelphia (The Filtration Society, 2 Woodstock Rd, Croydon, Surrey, UK).
 13-17 September, Chromatography,
- 13-17 September, Chromatography, London (Chromatography Discussion Group, Trent Polytechnic, Burton Street, Nottingham, UK).
- 19-25 September, Photosynthetic Prokaryotes, Bordeaux (G. Stanier, Institut Pasteur, 28 rue du Docteur Roux, 75724 Paris Cedex 15, France).
- 14-16 September, Neurophysics, Cambridge (Dr G. Leng, ARC Institute of Animal Physiology, Babraham, Cambridge, UK).
- 15-17 September 1st Meeting of the British Liquid Crystal Group, Southampton (Dr J.W. Emsley, Dept of Chemistry, The University, Southampton, UK).
- 20-24 September, Carbon '82, London (Society of Chemical Industry, 14/15 Belgrave Square, London SW1, UK).
- 20-24 September, Antibiotics and Antibiosis in Agriculture, Nottingham (Prof. M. Woodbine, University of Nottingham, Faculty of Agricultural Science, Sutton Bonington, Loughborough, Leicester, UK).
- 20-24 September, 10th Molecular Crystal Symposium, Quebec (Dr D. Chartrand, National Research Council of Canada, Ottawa, Canada K1A OR6).

nature

Does biotechnology have a price?

The five United States universities represented at the meeting to consider the commercialization of genetic manipulation have issued a statement whose omissions are more significant than its content.

Last week's gathering of five university presidents and their entourages at Pajaro Dunes in California was a predictably civilized occasion it would seem, but hardly productive. The communique afterwards put out (see Nature 1 April, p.381) delicately acknowledges that the interest of universities in the commercial exploitation of genetic manipulation may occasion difficulties; makes a few general observations to the effect that universities should not let corporate or individual relationships with external commercial interests interfere with teaching and research; says that universities holding patents should be free occasionally to award exclusive licences; and concludes that it will in most circumstances be unwise for universities to invest financially in companies in which faculty members have a direct and substantial interest.

These unremarkable observations are offered as a contribution to what the five presidents rightly expect will be a continuing discussion of the propriety of arrangements between universities and external commercial interests. Because groups of university presidents are free to spend a few days at the seaside in each other's company without issuing an account of what they talked about, the Pajaro Dunes statement is something to be grateful for. Indeed, the fact of the meeting implicitly and the communique explicitly acknowledge that the public interest in the commercialization of academic research overrides the interests of individual universities. So why does the communique fail even to mention the immediate and perplexing issues with which universities must grapple in the years ahead?

Take secrecy. One of the most obvious consequences of the interpenetrating networks of commercial agreements being forged with external commercial interests by institutions, departments and individual academics is that the free flow of ideas within laboratories will be inhibited by the fear that to say too much will be to hazard a commercial advantage. The Pajaro Dunes communique acknowledges the risk, and says that agreements with external interests should be "so constructed as not to promote a secrecy that will harm the progress of science. . ." But how, in the real world, is that to be accomplished?

What happens, for example, if two members of the same academic department are also the prime movers in two separate commercial companies? Or if two close colleagues are consultants for competing commercial concerns? Or if the research carried out by one group within a laboratory is supported by a commercial organization by means of an agreement that gives the company first refusal of patent rights? In each case (and others), close colleagues will be tempted to bite off their tongues for fear of providing clues revealing of the commercial interests of their sponsors. Previously innocent academics, probably less skilled than professional consultants at distinguishing between proprietary and general information, are likely to behave like clams even in discussions of such general questions as the mechanisms by which eukaryotic genes are regulated. For the time being, in any case, (the kinds of questions that commercial companies are likely to be asking of those who work for them as consultants.) But in most universities and academic departments, the tongues of externally-interested academics will be further tied by the knowledge that they cannot know which of their colleagues is working privately for which competing organization.

Disclosure of external interests is therefore an essential part of

the process of preserving the civility of those parts of the academic research enterprise recently discovered to be commercially important. But disclosure to whom? And to what extent? Will it suffice that the chairman of a department should know for whom his immediate colleagues are moonlighting? Will chairmen in their turn shoulder the responsibility implied in the confidentiality of the disclosures made to them of making sure that putatively competing academics are aware of each others' outside interests? Or might it be better that disclosure should be more general? And is there not then a danger that students would be apprised of information that would be an excuse for occupying the departmental chairman's office on some sunny afternoon when there is nothing else to do? It is no wonder that the participants in the meeting at Pajaro Dunes steered clear of questions such as these in their published statement. Questions such as these are nevertheless prominent among those universities that must decide for themselves in the next few weeks or months.

The Pajaro Dunes communique would have been more helpful if it had openly acknowledged that problems such as these exist. It should also have recognized that the difficulties occasioned by biotechnology differ only in degree from those with which universities have learned, however uneasily, to live. For biotechnology, the commercial exploitation of genetic manipulation differs for the time being from more familiar branches of technology only in the speed with which a bright idea may be translated into a patentable invention. In other fields, chemical engineering for example, the process of innovation consumes more time and is less certain. But it is well understood that much of the research carried out in university laboratories, in computer science for example, has led in recent years to important industrial improvements and, as a consequence, to a close interdependence between academics and industrial partners. The result, especially in the United States, is that there is now a modest army of academics acting as consultants to industrial companies while agreements between companies and academic laboratories for the support of basic science in return for beneficial treatment in the exploitation of innovations are by no means unprecedented or

From this it follows that universities cannot hope to devise rules for the proper exploitation of basic research in genetic manipulation unless these also apply to the regulation of other branches of technology. It is, however, plain that in biotechnology, more explicit rules for deciding how academics and academic departments should conduct themselves are necessary. Within departments, seemly rules about disclosure are plainly needed if academics are to continue to talk to each other without restraint. For universities, it is also essential that the basis on which agreements for the support of research by outside companies should be publicly disclosed. Failure in this respect will put in hazard public trust in the whole of higher education. And universities must more zealously than at present ensure that the education of students, graduate students in particular, is not distorted by the commercial extramural interests of those who are supposed to teach them. If this implies that the research projects on which graduate students are engaged should not be determined exclusively by individual members of a university faculty, the restriction of individuals' academic freedom that would imply would be a small price to pay for the preservation of the

reputation of universities to put the interests of their students first. Individual universities may not be too hard-pressed to devise rules for regulating what happens in departments with an interest in biotechnology. The difficulty will be to ensure that these can be applied across the board.

Some thought should also be given to the question of why the commercialization of basic research has recently thrown up so many problems. Government support for basic research is shrinking everywhere, while universities are being urged to look to industry for sponsorship. Universities and individual academics are being driven into the arms of those companies farsighted enough to recognize that they have much to gain from partnerships like these. There is much to be said for finding ways of turning academic discoveries into prosperity for the wider community. But while some academics appear genuinely to be excited by the challenge of turning their bright ideas into business enterprises, others appear to be at least as much intrigued by the prospect of monetary rewards. Explanations, or excuses, are not hard to find. Compared with their students who make a success in industry, academics are scandalously paid, for example. But has the traditional loyalty of academics to the institutions which employ them been eroded? And if so, what will be the consequences of that? It is a fair guess that the university presidents who met at Pajaro Dunes two weeks ago would have been fully conscious of this disturbing thought.

The Falkland War

The British Government hopes that diplomacy will avoid a war with Argentina. How?

The next few days are bound to have an air of unreality not merely for those who live and work in Britain or Argentina but for the rest of the world. A small British naval force is sailing to the South Atlantic with the intention of liberating the Falkland Islands from their occupation by an Argentinian force last weekend. The military task is formidable, for it is bound to be more difficult to dislodge an occupying force than it would have been to prevent it from landing in the first place. So too is the diplomatic task, for the government of Argentina has repeatedly declared its intention of staying put. Sensibly, however, the British government has promised to use the next few days for seeking some kind of solution. What might this be?

The facts are clear. There is no impartial body of opinion that disputes the illegality of what the Argentinian government has done. Moreover, the doctrine advanced in Buenos Aires that the Falkland Islands belong to Argentina because of their proximity is a dangerous doctrine, as the case of Ulster in Ireland shows. The Argentinian action in the Falkland Islands might have been seen in a different light if the 1,800 inhabitants of the islands had shown the slightest inclination to opt for Argentinian rather than British citizenship, and if Britain made no use of the territory (which serves as a staging post not merely for commercial vessels but for British Antarctic expeditions). In this sense, the British presence in the Falkland Islands is beyond reproach. The problem is to reconcile this with the apparently implacable conviction of the government of Argentina that the Falkland Islands belong to Argentina.

Sovereignty is a heady concept, for which people are all too willing to kill each other. In the weeks ahead, the governments of Britain and of Argentina will also know that their own survival may depend on how things turn out in the Falkland Islands. So should they not think of trying to reach a settlement of this wasteful conflict by more old-fashioned methods than the use of military technology. Specifically, should not Britain think of offering to sell the Falkland Islands to Argentina in much the way in which Alaska was traded by the Soviet Union to the United States? The price, of course, would be high. Not merely would the 1,800 people of the Falkland Islands have to be compensated, but the British government would have to be recompensed for the loss of the benefits it now enjoys from possession of this out-of the way place as well as for the benefits that may in the future accrue.

Rewiring Britain

The Government, after a decade of indifference, is now too quickly embracing cable television.

As Paul on the road to Damascus, the British government has suddenly been converted to the belief that it will be socially beneficial if a substantial part of Britain can be covered with cable television systems. Two weeks ago (see Nature 25 March, p.282) the Department of Industry surprised most British taxpayers with an announcement that by the end of the year, it will have worked out a scheme that will allow commercial companies to invest in cable television systems. Between now and then, the government hopes, a committee under Sir John Hunt, one of the many exsecretaries of the Cabinet still in active service, will have worked out a set of rules for regulating this business, new for Britain. No doubt the government has it in mind that many voters at the next general election will go more cheerfully to the polls if they are able to return to a wider choice of television signals than at present.

The directness of the government's change of heart is remarkable. For the past decade, the Home Office has allowed only a few local experiments with cable television. Part of its reluctance is explained by its wish not to encourage competition with the development of the national broadcast television service. Thus, in the autumn and after years of argument, a fourth channel of broadcast television will take the air financed by the revenues from commercial advertising. Hitherto, the government has listened to the pleas of the Independent Broadcasting Authority that the success of that enterprise should not be jeopardized by allowing advertisers competing outlets for their cash. That principle, it seems, has now been abandoned. At the same time, the present British government has plainly decided that it can no longer allow itself to be restrained by the squeamishness of the principal opposition party about paytelevision. Subscribers to the proposed cable television networks will be able to watch on their screens whatever they can afford to pay for.

But what? This is where Sir John Hunt's committee will run into trouble. Working against the government's clock, the committee will be tempted to follow precedents established overseas, in the United States especially. It will thus be tempted to insist that any new cable system should distribute the four national television channels that are at present adequately served by conventional broadcasting. Even though some of the would-be operators of cable systems are likely to protest that such a requirement would be pointless, in the long run substantial benefits should accrue. The other obvious temptation will be to follow the common pattern in the United States which requires cable systems to provide one or more channels free to those local interests believing they have something to say to the public at large. That is a temptation to be resisted, for the experience of the United States has shown that people linked with cable systems vote with their tuning knobs to watch something else in preference. In the long run, the public interest will be best served by taking its chance with other interests.

The most contentious issue, however, will be that of how the content of signals put out on the new cable systems should be regulated, and by whom. There will be a temptation to set up some public body to ensure, for example, that nothing broadcast by the new cable systems can give offence to those who at present act as custodians of public morality. This, too, is a temptation that should be resisted. For the most obvious difference between cable systems and conventional broadcast channels is that the channel capacity of cable is much greater than that of the atmosphere. While it will remain important that the national television service should conform with rules that are understood and accepted, people linked with cable television should be allowed to receive whatever signals they wish — and which they are prepared to pay for. The danger here is that the potential operators of cable networks, anxious as they are to encourage the government in its new resolve, will meekly agree to censorship that will not afterwards be easily removed.

German cancer centre criticized

Report urges major changes in constitution

Sweeping changes at the Deutsches Krebsforschungzentrum (DKFZ) in Heidelberg have been recommended by the international commission appointed by the German Minister for Science and Technology. The proposed changes would invest the director of DKFZ with executive power, the lack of which caused the resignation of Professor Hans Neurath last year (see Nature 293,252; 1981).

The report, published last week by the ministry, is highly critical of the overall performance of DKFZ in basic research. Although acclaiming the quality of research by some investigators in the centre's eight institutes, particularly those of cell biology, immunology and virology, the report says that in a large number of the institute's 39 divisions, the research work is merely reliable and unimaginative. And the output of a number of scientists has amounted to little more than one unremarkable paper a year for the past decade: Overall "this does not indicate that the quality of research commissioned in DKFZ is in any way outstanding",

The centre is also criticized for its lack of collaborative ventures and its failure to take a lead in arranging multi-centre clinical trials. The commission considers that the largest cancer centre in Western Europe, employing more than 1,000 staff at an annual cost of DM90 million (£20 million), should do better.

Two main factors are said to account for the mediocre performance of DKFZ. The first is lack of effective external peer review. The second is that the constitution of the centre is such that the director does not necessarily have the power to bring about changes. "His proposals may be blocked or intolerably delayed and his position can be undermined by other proposals . . . from the Scientific Council" (a committee made up of the heads of institutes and an equal number of elected staff members). It was intolerable difficulties of this kind that Professor Neurath had "bravely attempted to overcome", says the report.

The resolution of this problem, says the commission, is of paramount importance to the future of DKFZ. It proposes that DKFZ's director (officially chairman of the executive board) should also serve as chairman of the Science Council. In this way the director could no longer be subordinate to his staff and could assume authoritative direction of the centre.

In the commission's view, the Science Council would still be a powerful advisory group whose majority view its chairman, the director, could ignore only at his peril (his is the only senior post without tenure).

On peer review, the commission says there is no adequate system to ensure that resources are wisely distributed among a staff most of whom have unlimited tenure. Some form of peer review has periodically been carried out by the centre's Science Advisory Council (Wissenschaftliche Beirat) but the council is not required by the constitution to conduct such reviews, is too small to perform the job adequately and is open to influence from the staff.

The commission proposes that the Science Advisory Council be replaced by a committee of eight independent scientists who would be responsible for arranging regular external peer reviews of all institutes and divisions of DKFZ. The same independent scientists would also fill the eight places for scientists on the Kuratorium. No longer would three of these posts be filled by elected members of

DKFZ. The commission considers that staff members have no place on the executive board of the institute that employs them whereas the director, who is not a voting member of the Kuratorium, should be on the board.

It is on the question of "worker participation" that there is bound to be political opposition to change. Staff representation on the Kuratorium began in 1975, when it was being widely adopted in both public and private concerns throughout Germany. Dr Wolfgang Finke, now chairman of the Kuratorium, would prefer to see it retained on the grounds that the presence of staff scientists on the Kuratorium has been a useful channel of information between the staff and the trustees. If there is a problem, he feels, it arises from the individuals concerned, not the principle.

Apart from that point, Dr Finke believes that the Kuratorium should give serious consideration to all of the commission's

Yale says no to a \$33,000 grant

Washington

Yale University last week reluctantly bit one of the hands that feed it, and declined a \$33,000 grant offered by the National Science Foundation for one year beginning on 1 May. By this unprecedented act, the university also gave renewed publicity to the fact that one of its faculty, mathematics professor Dr Serge Lang, strongly objects to the US government's requirement that recipients of federal research grants should produce detailed reports of the amount of time they spend working on federally supported projects.

Dr Lang described himself on the telephone last week as one "who knows more about A21 than anybody else". The reference is to the much disputed circular A21, issued by the Bureau of the Budget (now the Office of Management and Budget, OMB) more than twenty years ago. Yale's refusal of the grant, the renewal for a third year of its support for Dr Lang's project "Number theory and elliptic curves", is due to his refusal to accept the reporting requirements.

Dr Lang also said last week that his objections to "effort reporting" were unlikely to be met by the revision of A21 now being considered by OMB, which are substantially those agreed last year between OMB and groups such as the American Association of Universities and the Council of Scientific Society Presidents.

Since the publication of the proposed revision in the *Federal Register* on 7 January, there has been a steady flood of protests from academic scientists that even the proposed revisions do not meet the objection that it is meaningless to attempt

to distinguish between time spent on teaching and time spent on research. As published, the revision of A21 would do away with the requirement for a detailed account of the time spent on various activities by faculty members supported partly by federal funds. Instead, three alternative methods of accounting for effort devoted to federal projects are proposed, one of which would allow of a certifying signature by "a person having direct knowledge of the work" and not by the faculty member as such.

In the draft revision, however, OMB has not conceded the principle urged by many academic scientists that there are circumstances, research by graduate students for example, in which it is literally meaningless to seek to distinguish between research and teaching. Opponents of OMB's accounting ambitions are able with relish to quote on this point from the report of a task force in 1968 under Cecil E. Goode, then an official of the Bureau of the Budget.

Part of the reason why A21 has become a source of contention in the past three years is that government auditors have been seeking to use it as a means of quantifying (and presumably limiting) the indirect costs added to research grants as compensation for the administrative work carried out centrally by a university. Yale was not impelled to decline the first two instalments of Dr Lang's three-year grant because of a dispensation which expired at the beginning of this year.

Under the terms of the grant offered, Yale would have been paid two-ninths of Dr Lang's salary by way of compensation for work done during the long vacation.

recommendations. He will no longer be its chairman when the Kuratorium comes to consider the future of DKFZ on 21 June because, from 1 May responsibility for the centre will be shifted as part of a reshuffle of responsibilities in the ministry. It is likely that the new chairman will be Dr Güentsch.

Professor Hans Neurath, now back in the University of Washington, Seattle, also welcomes the report, describing it as "excellent, clear and succinct".

Reaction to the report at DKFZ is hard to gauge, but inevitably mixed.

Only after the 21 June meeting of the Kuratorium will it be known which of the commission's proposals will be adopted. One problem is that since Professor Neurath's resignation, DKFZ has been without a real director, although Professor Otto Westphal was appointed acting director from 1 March until the end of 1982. Another is that there is almost certain to be strong resistance to many of the proposals from within the centre. And it does not help that the politicization of the centre's difficulties comes at a time when the German government has matters of far greater importance on its plate - survival for example.

Thus, whereas the commission recommends that proper peer review of DKFZ starts without delay, with at least three institutes to be reviewed by the end of the year, there is a good chance that the peers will need topcoats rather than safari suits by the time they descend upon Heidelberg.

Peter Newmark

Europe's nuclear power

Border incidents

Brussels

A bizarre mixture of Molotov cocktails and red and yellow balloons was released at a demonstration on 27 March when Belgian environmentalists protested at the continuing construction of four French nuclear power stations at Chooz, close to the Belgian border. Protests against the Chooz reactors are now a regular part of Belgian life. Some weeks ago, the Belgian Embassy in Paris was occupied by two Belgian senators belonging to the environmental party, and demonstrations on the border are now promised on the last Saturday of each month.

While there is no sign that the protests will influence the French government's determination to press ahead with the four 1,300 MW reactors to be built on the Meuse at Chooz, they may affect the Belgian government's willingness to participate in the project. Given the prospect that Belgium will have to rely on nuclear power for half of its electricity production by 1985, the government must either sanction the nuclear power construction in Belgian or join in the Chooz project.

For a time, the government sought to obtain electricity and to counter the protests by linking participation at Chooz

with the stipulation that the French reactors should be built to Belgian safety standards. This suggestion has, however, been rejected by the French on the grounds that construction costs would be increased.

The issue has thus been invested with national pride. The Belgian government is being told, most vociferously by the Flemish-speaking population near the border, that it has allowed itself to be bullied by its larger neighbour. France, on the other hand, cannot admit that its own safety standards for reactors are inadequate simply because the Belgian standards are more stringent. France has also declined to reveal details of the reactors to be built at Chooz beginning in December, and to reveal plans for the discharge of some low-level waste into the Meuse.

There is a chance that the European Commission may be able to help. The revision of Article 37 of the Euratom Treaty soon to be adopted would require France to seek approval for its plans for radioactive waste disposal six months before construction at Chooz begins. So far, however, there is no sign that France is prepared to let the commission interfere or to engage in consultations with Belgium.

The Belgian government is in any case itself divided over the country's energy plans. The energy minister, Mr Etienne Knoops, is anxious that Belgium should have more nuclear power stations and keen on participation at Chooz. He is opposed by the science and budget minister, Mr Philip Maystadt, who wants the decision on Chooz put off until the parliamentary debate arranged for the end of May — after the 16 April deadline for a decision on participation will have passed.

In the end, Maystadt's arguments are likely to prevail. Belgian utility companies argue that it would be more sensible to invest in a Belgian project than in Chooz, especially because it is now estimated that Belgium will need to build thirteen 1,300 MW reactors by the year 2020. In any case, the cost of electricity from the Chooz plant quoted by the French is unpalatably high.

Jasper Becker

•Environmentalists are also on the move in France — on foot, in fact, between the site of the near-complete French fast breeder reactor, Superphénix, in the south of France, to Paris, where they hope to meet President Mitterrand on 18 April to protest against fast breeder development. A hundred demonstrators gathered on Sunday near Superphénix in the march, which has begun peacefully. This is in marked contrast to the rocket attack on Superphénix last summer, and the violent demonstrations of 1977 in which one demonstrator died. Brice Lalond, national secretary of the French Friends of the Earth, addressed the marchers. "Nothing has changed since 10 May", he said. referring to the election of Mitterrand as President of France and his socialist Robert Walgate government.

United States astronomy

High priorities

Apparently unabashed by the austerity now rife in Washington, the long-awaited Field report on astronomy and astrophysics in the 1980s will include a \$1,900 million (at 1980 prices) shopping-list, mostly for new equipment. A draft of the report (to be published next month) says that these plans would require that the astronomy budget of the National Science Foundation (NSF) in the 1980s should be 30 per cent greater in real terms than in the 1970s.

The report has been prepared by the Astronomy Survey Committee under the chairmanship of the director of the Harvard-Smithsonian Center for Astrophysics, George Field. The committee was set up in 1978 by the National Academy of Sciences (NAS) to assign priorities to a wide range of astronomical projects based on the ground or in Earth orbit, but excluding planetary missions and deep-space probes.

Field report recommendations Decade cost (1980 \$ million) Major new programmes, in order of priority 1. Advanced X-ray Astronomy 500 Facility (AXAF) 50 Very Long Base-line (VLB) Array 100 3. New Technology Telescope (NTT) 4. Large Deployable Reflector in Space 300 950 Modest new programmes, in rough order of priority 1. Augmentation of Explorer satellite programme 150 Far UV spectrograph in space 60 Space VLB antenna Optical/IR telescopes (2.5 m) 20 Advanced Solar Observatory in space 200 100 Cosmic ray experiments Search for Extraterrestrial Intelligence 20 750 Small new programmes 4 10 m submillimetre-wave radio antenna Other important programmes Spatial interferometer for mid-IR 3 High precision optical astrometry 3 programme Temporary programme to maintain astronomical expertise at 10 universities 20 Total expenditure over decade on new project 1,720 Total expenditure on "prerequisites 190 (theory, data analysis, etc.) Grand total \$1,910 million

In its review of astronomical problems and the best ways of tackling them, the report assumes the existence of such shuttle-dependent projects as the Space Telescope, the Gamma-Ray Observatory, the Shuttle Infrared Telescope Facility, the Solar Optical Telescope and the ground-based 25-metre millimetre-wave radiotelescope, all but the last of which appear to have survived in the US Administration's budget for 1983.

For the 1980s, the committee recommends that the highest priorities should be given to the Advanced X-ray Astrophysics Facility (AXAF) satellite, a Very Long Baseline (VLB) array of radiotelescopes, a

giant New Technology Telescope (NTT) in the 15-metre class and a 10-metre sub-millimetre-wave antenna. All these devices would contribute to the solution of the astronomical problems highlighted in the report — the large-scale structure of the Universe, the evolution of galaxies, violent events (such as supernovae and processes in active galaxies and quasars), the formation of stars and planets and solar and stellar activity.

In the committee's view, AXAF is a must at a cost of \$500 million. The VLB has beaten the 15-metre telescope into second place because it would require considerably less preliminary development and would have by far the best angular resolution of all techniques - 0.3 milliarc seconds possibly allowing the resolution of the nuclei of active galaxies and quasars at radio wavelengths. But because of the tremendous potential light-gathering power of the 15-metre telescope, an order of magnitude larger than present telescopes, the committee puts that on as high a level of scientific desirability as any other project examined.

The committee also urges increased support for what it calls prerequisites — instrument design (including a request for declassification of certain infrared detectors), theory, data analysis, computing facilities and laboratory astrophysics. To handle the data from AXAF, the committee recommends that a special institute be set up in support of the satellite, analogous with the Space Telescope Institute. As a consequence of its recommendations, the committee sees the need for an increase in personnel at all levels.

In his foreword to the report, Herbert Friedman, chairman of the Mathematical and Physical Sciences Assembly of NAS, stresses the need for an increase in the relative contribution of ground-based astronomy and, consequently, the NSF contribution. He also says that the technology of new developments in astronomy is dependent on but will also contribute to areas of science and to industrial and military applications.

In the present climate, it is hard to see the astronomers having many major desires fulfilled. Of the major recommendations of the influential Greenstein report, the 1972 predecessor of the Field report, only one - the VLA radiotelescope - was implemented in the less austere 1970s, for example. The Field committee emphasizes, however, that the level of expenditure it requests is equivalent in real terms to that which followed the Greenstein report. Moreover, Dr Friedman points out that they are hoping "that the purposes of the present fiscal policies will be achieved in a reasonably short period and that a healthier base of federal scientific support will then be restored". But if the Greenstein report can be viewed as a precedent, X-ray astronomers have struck lucky. Philip Campbell

High-energy physics

Tunnel vision

A legal obstacle to the construction of LEP, a European particle accelerator which should put European physics in the 1990s well ahead of the United States, has been removed. But the shouting is not yet

LEP - a large electron positron collider - will straddle the French-Swiss border in the plain of Geneva, linking with existing machines at the European Centre for Nuclear Physics, CERN. CERN has won cash and approval for the project from its member states, which include France and Switzerland, but the problem lately has been how to carry the project through local planning procedures in France and Switzerland. French environmentalists had managed by a legal technicality to block construction of an important exploration tunnel, but now the French court of appeal, the Conseil d'Etat, has finally ruled that the tunnel can go ahead after all.

This, however, is only a minor victory. The main justification for the tunnel was that it would provide an escape route for both engineers and water if the main LEP ring — which originally led right under the 1,000 m high peak of the Jura mountains — encountered high pressure water in the Jura limestone. But now the LEP ring has been shuffled almost entirely out of the Jura, by tipping it on its side (see figure), so water pressures will be lower. It will also now be possible to intervene from the surface if people are trapped.

However, there are still geological and political problems to solve. Geologically, the 3 km of LEP that will still lie in the Jura limestone lie entirely in the *piémont*, near the boundary with the sandstone of the plain. This rock is likely to be traversed by caverns and faults, and although vertical borings along the new route have revealed nothing serious, uncertainty persists.

Politically, the obstacle may still be the Association gessienne de protection de la Nature, the local French environmental organization presided over by M. Jean-Roger Honorat, the mayor of Echenevex. This group blocked the construction of the exploration tunnel, and although CERN has wooed it ever since, it remains suspicious.

The group will play an active part in the French planning process now under way.

New cancer research award

The 1982 Bristol-Myers Award for Distinguished Achievement in Cancer Research has been awarded to Dr Denis Burkitt (of Burkitt's lymphoma) and Dr Michael Epstein (of the Epstein-Barr virus). Their \$50,000 award was presented to them in New York this week.

Dr Burkitt was Government Surgeon in Uganda some twenty years ago when he proposed, from epidemiological studies, that an infectious agent caused childhood lymphoma in Africa, Dr Epstein heard Burkitt speak in London

Epstein (left) and Burkitt

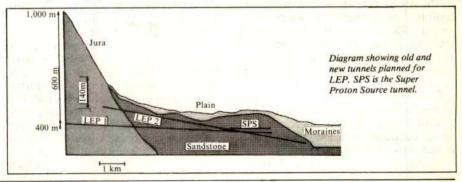

in 1961 and within two years had isolated the infectious virus that causes the lymphoma.

Burkitt is now an honorary senior research fellow at St Thomas's Hospital in London. Epstein is professor of pathology at the University of Bristol. And Yvonne Barr, in case you were wondering, is an Australian housewife.

Peter Newmark

The French ministry of foreign affairs, with which CERN must deal, now has CERN's final environmental impact statement, and under French planning law will act on CERN's behalf. There is to be a local public inquiry at which anyone in the region may present his views. CERN itself will be represented at the inquiry only if needed to explain technicalities; it has no right to plead. Eventually the results of the inquiry and files of submissions will be returned to Paris for a decision by the Conseil d'Etat.

Meanwhile, CERN is about to invite tenders for the construction of the tunnel, which should be in by the autumn. A decision from the Conseil d'Etat is not expected before the end of this year but a delay beyond that would mean LEP would not be producing particle collisions by the end of 1987 as planned. Robert Walgate

Agricultural Research Council

Savings plans

The British Agricultural Research Council (ARC) is still in a fix about its budget for the next three years. Plans to find all the necessary economies to meet the expected shortfall in its government grant at the Animal Breeding Research Organization (ABRO) and the Long Ashton Research Station have been abandoned. A decision on the future of the two institutes, which was to have been taken at the end of last month, has been put off to the end of April, and the council has set up a "core group" to look for comparable savings elsewhere.

ARC had originally planned to save the expected £3 million deficit in its annual budget by cutting research on food, beverages and fruit at Long Ashton and by cutting back ABRO to fundamental animal genetics. It has, however, found its hands tied by the Rothschild customer-contractor principle, whereby the Ministry of Agriculture (the customer) commissions a substantial proportion of research in ARC institutes (the contractors). The ministry, aided by the livestock industry, seems to have objected strongly to the plan to cut ABRO to one-fifth of its present strength. Such is the colour of the ministry's money, however, that at one stage it had almost persuaded ARC to cut fundamental rather than applied research. In the event, ARC last week produced a revised plan that may get it off that hook.

The revised plan being circulated for consultation before a final decision on 20 April entails a 50 per cent cut in ABRO's annual budget, from £2.25 million to £1.2 million, by 1984–85, but keeps the balance between fundamental and applied research roughly the same as now. Work on the long-term breeding of sheep and pigs and on the efficiency of dairy cows would continue, as would several areas of animal genetics. ARC says that it may also find a further £0.4 million for research in molecular biology later on. The council clearly hopes its new plan will have an easy passage.

The proposals for the Long Ashton Research Station, which have caused less of a stir, are likely to stand. Hence some research will probably be moved to the East Malling Research Station and the fruit industry is being asked to increase its support for the remaining programmes.

The debate over the future of the two institutes nevertheless has wider implications. ARC's own staff has complained that the process of regularly reviewing research programmes is not sufficiently open. It is also clear that the council needs some way of deciding priorities within as well as between institutes. But the most telling lesson of the past few days is the council's discovery that under the customer—contractor principle, the customer is ultimately (if not always) right.

Judy Redfearn

Not enough toxicologists in Europe?

The European Science Foundation (ESF) and the European Medical Research Council (EMRC) have announced a new programme for research and training in toxicology. A number of awards will be made in 1983 along the lines of ESF's existing brain research programme.

EMRC is basically a talking shop for ESF, representing members of the governing bodies of 14 Western European medical research councils who meet twice a year, and directors of the regional office of the World Health Organization and of the National Institute of Health in Bethesda, Maryland have a standing invitation to attend meetings. Toxicology has been a major interest of EMRC since it was established in 1971, and now nine members of EMRC have put up the money for the toxicology programme; the 1982 budget is FF700,000 (£63,600).

Although the demand for toxicologists in industry and government is growing rapidly, toxicology remains an ill-defined subject which may mean different things in France and, say, Denmark.

EMRC has recommended that priority should be given to mechanisms of toxicity and the epidemiology of exposure to chemicals. It also emphasizes the need for more research in toxicology and the inclusion of toxicology in the university curriculum. In the United Kingdom, for example, toxicologists are drawn mainly from pathology and biochemistry, and the subcommittee report on which the ESF programme is based is impressed with the complaint from industry that university graduates lack practical training in toxicology.

As well as travel and subsistence grants for training courses, ESF plans to award one-year training fellowships to graduates from toxicology-related disciplines. There will also be renewable fellowships for people already working as toxicologists for projects involving collaboration with teams abroad.

ESF is optimistic about the programme. It is to be hoped that the length of time it has taken to set up the new programme is not indicative of the pace at which all collaborative European research will develop.

Jane Wynn

Soviet science and technology

Practical slant

The Soviet Academy of Sciences seems to be planning a more direct interest in production research, according to Dr Anatolii Aleksandrov, the president, in his address to the academy's annual meeting. The academy's increased participation in technological projects in the past eighteen months seems to be connected with the appointment of Dr Gurii Marchuk, formerly chairman of the Siberian branch of the academy, as head of the State Committee for Science and Technology.

When Dr Marchuk moved to the state committee, which is responsible for applied research and its implementation, he urged greater use of the academy's talents in implementing research results in production — thus bridging what has become a major planning gap.

The academy's new practical slant is clearly approved by Dr Aleksandrov, who has often stressed that the Soviet Union is potentially independent of foreign research and development. By contrast, the chief academic secretary of the academy. Dr Georgii Skryabin, told the annual meeting of his regret that the deterioration of the international situation has led to reduced contact with the West. He particularly deplored the cutback in exchanges with the United States - although the US National Academy of Sciences had asked for talks to continue on international security and arms control. Contacts with the United Kingdom, on the other hand, had, he said, "become more active".

University research funding

Line of defence

Washington

US universities and colleges continue to benefit from Washington's current enthusiasm for increasing its expenditure on military technologies and related national security needs. A subcommittee of the House of Representatives has now approved a provisional bill, said to have wide support within the Administration, which would allocate up to \$100 million a year to improve facilities in higher education institutions in technical subjects important for security interests.

The explicit purpose of the legislation is to increase the ability of the United States to meet both its immediate defence needs and the technological demands that would be created by a prolonged war.

The legislation is supported by the Department of Defense, the Department

"HERE'S YOUR GRANT—THIRTY THOUSAND PIECES OF SILVER."

of Commerce and congressmen representing areas of the United States which are suffering hardest from the current recession.

Furthermore, according to a report published last month by the Defense Science Board (DSB) on the state of the nation's research universities and their ability to absorb increased military research funds, many universities which had rejected close involvement with the Pentagon in the late 1960s and early 1970s are now experiencing a change of heart.

The DSB study has been used by the Department of Defense to justify the major increase in university research funding which it is asking Congress to support. In his budget request last month, President Reagan proposed a 30.5 per cent increase in university basic research funded by the Army, to a total of \$92.1 million; a 36.9 per cent increase in such research funded by the Air Force, to reach \$89.7 million; and a 17.2 per cent increase in Navy funding. Basic research supported by the Defense Advanced Research Projects Agency would rise to \$8.4 million, a 21.7 per cent increase. Many of the extra funds would go explicitly to raise the level of effort in the mathematical sciences, electronics, chemistry and engineering conversion.

The details of the Defense Department's budget request reflect some of the science board's conclusions and some of the universities' concern. In response to complaints about the declining state of the universities' research facilities, the department has announced its intention to allocate \$150 million over a five-year period to improving research instrumentation. Each of the three major services will put aside \$10 million a year for this purpose.

The department is also attempting to overcome the increasing difficulty of universities in retaining top graduates in fields such as engineering by setting up a new graduate fellowship programme. Stipends will be \$12,000 a year — about 50 per cent higher than comparable awards made by the National Science Foundation — and the services will, in addition, provide affiliated universities with \$8,000 a year to cover tuition and fees.

The initial plans are to award about 125 graduate fellowships in the fiscal year 1983. which starts on 1 October 1982, costing the Department of Defense about \$2.5 million. Dr Jack Crowley of the Association of American Universities has said that the association warmly supports both the proposed funding for research facilities and the new fellowship programme.

If Congress does grant the extra funds there is unlikely to be any shortage of applications for the additional grants. With support for basic research from other agencies by falling in real terms and with industry unlikely to be able to make up much of the shortfall, the universities are looking to the Department of Defense as the only significant alternative source of support.

David Dickson

Oceanographic research

In the black

At a time when many groups are hard pressed to support large projects, a team from the UK Institute of Oceanographic Sciences (IOS) has just returned from a successful six-month cruise on which it earned more than £250,000 in foreign currency. IOS, now run by the Natural Environment Research Council, has been able to share the cost of its unique side-scan sonar project GLORIA (Geological Long-Range Inclined ASDIC) by combining its interests with those of several research groups abroad. With the ability to scan a swathe of the ocean floor almost ten times wider than conventional deep-tow sonars, the equipment is quicker and cheaper than other survey techniques, and many groups overseas are apparently eager to use it.

Research on this multi-project charter—
the first long voyage to use GLORIA—
was strongly oriented towards commercial
applications, principally oil exploration
and radioactive waste disposal. The UK
Department of Energy commissioned the
first part of the voyage, with an extensive
survey off Newfoundland aimed at
completing a reconstruction of the North
Atlantic during the Cretaceous to help

GLORIA aboard the trawler Farnella

assess the oil potential of Britain's continental shelf. The other British project, from the Department of the Environment, was an investigation of the possible disposal of high-level radioactive waste under the sea bed. Searching for specific sites is not the primary objective at present; the department is more interested in using GLORIA's ability to distinguish fine textural changes in the ocean floor to study the varying types of sea-bed environment.

One of the most exciting finds came from an area known as the Amazon Cone off the Brazilian coast. This is a huge pile of sediments washed out by the Amazon into the Atlantic, and is thought to be a potentially important source of oil. Submarine current meanders were for the first time observed to cut into the cone, giving new clues about processes of sediment deposition that may be relevant to the formation of oil-bearing structures. There has been great interest in this finding from petroleum geologists and from the Brazilian oil company Petrobras, which paid for this leg of the cruise jointly with

the Lamont-Doherty Geological Observatory of New York's Columbia University.

During the last leg of the voyage, on the way home from Miami, GLORIA was tested as a means of detecting deposits of manganese nodules, which at present can be located only by trial and error sampling. There seems to be a chance that GLORIA's sensitivity to slight variations in the reflectivity and roughness of the bed may offer a more direct means of location. United States scientists are said to have been impressed with the equipment.

David Millar

Soviet shake up

A regional earthquake monitoring centre has been opened in Dushanbe, in the Soviet republic of Tadjikstan, as a first step towards a seismic early warning system for the whole Soviet Union. Tadjikstan suffers several thousand earth tremors a year, and seismic activity is also very high in the neighbouring republics of Turkmenia, Uzbekkstan, Kirghizia and Kazakhstan.

The new centre will combine the resources of existing seismological centres of the Academies of Sciences of the various republics in the area, including a seismic testing ground covering 30,000 square kilometres in the northern Tien-Shan. The facilities of this site include wells 3,000 kilometres deep for studying subterranean waters in particular the radon content of such waters which has been observed to increase shortly before a tremor. Field stations at the site also monitor the Earth's magnetic field and telluric currents, while microdisplacements of individual crustal blocks are measured with lasers. Biological teams monitor the behaviour of snakes, ants and other fauna said to behave abnormally during the build-up to an earthquake.

In 1980-81 Soviet seismologists say they successfully predicted the occurrence of 13 earthquakes, including force 4-5 tremors in Dushanbe. The seismologists seem very open-minded to any suggestions of possible early-warning signals. Recent investigations have included the relationship of the amount of mercury vapour emitted from the Earth's crust, or present in subterranean well water, and an assessment of local folk lore which has it that a seismic shock is frequently preceded by overcast skies and dust-storms.

The heart of the Dushanbe centre will be a computerized seismological data bank, linking existing centres, to be augmented by links to new mobile seismic monitoring stations scheduled to go into production in the near future.

CORRESPONDENCE

The return of malaria to India

SIR - In their article on malaria resurgence, Chapin and Wasserstrom1 claim that the agronomic use of DDT led to the development of DDT resistance in mosquitoes and hence to a resurgence of malaria in India. However, the main cause of the rapid increase in the consumption of insecticides in India since 1970 has been their greater public health use in the wake of malaria resurgence2, and agricultural use of DDT has remained fairly constant during the past several years (see table). So the correlation between increase in DDT use and rice production (Fig. 1 of Chapin and Wasserstrom) is superficial and does not imply a cause-effect relationship. Similarly, noting static cotton production and increasing total DDT consumption, Chapin and Wasserstrom are incorrect to conclude that "more and more DDT must be sprayed simply to maintain a fixed vield'

The public health use of DDT in India has always exceeded its agronomic use, so although the agricultural use of insecticides has contributed to the resistance problem, blame must be shared by both agricultural and public health applications. And moreover, as multiple resistance in Indian mosquitoes to DDT, BHC and malathion is not cross-extending³, correlation between the use of a single insecticide (DDT) and malaria cases (Fig. 2 of Chapin and Wasserstrom) can only be spurious.

When seeking reasons for the present problems for malaria control in India administrative lapses are a factor which must be considered. Under the World Health Organization (WHO), moves in the 1950s to reduce Plasmodium transmission by attacking female mosquitoes via insecticide spraying, and to deplete the Plasmodium reservoir in human beings by treating patients with antimalarial drugs, were successful. However, this success was nullified because mosquito populations in the forests of Assam, Madhya Pradesh and Orissa were not taken into account. These populations were not affected by spraying of dwellings, so remained infective and gradually reintroduced Plasmodium to the now resistant mosquito population. Here it should be noted that Chapin and Wasserstrom use "resistant mosquito populations" and "malaria" as synonyms, when in fact resistant mosquito populations existed harmlessly in India for a decade becoming a hazard only in the presence of Plasmodium.

In attempting to find ways of overcoming India's malaria resurgence, an example to learn from is that of California, where use of physical, cultural and biological techniques as adjuncts to chemical control has both prevented malaria resurgence and reduced insecticide use to about a third of the levels used a decade ago⁴. Such techniques have substantially cut the costs of mosquito control in California, and if they were adopted in developing countries, savings could be used to replace DDT with the alternatives which have not been used before because of the high costs.

Although what appears clear with hindsight may in fact have been difficult to foresee, it seems fair to say that WHO was slow to recognize the limitations of residual

insecticides. WHO placed prime reliance on chemical control and gave low priority to nonchemical control measures so that when malaria control began to deteriorate, no proven alternatives were available to supplement insecticides. A review of literature on mosquito pest management strategies5 reveals that WHO's efforts in this line started in the 1970s, by which time mosquito resistance to insecticides had become rampant. Though it is difficult to differentiate between the residues from insecticide use in agriculture and public health, preliminary studies6 indicate that DDT and BHC use in malaria control may be responsible for the serious pollution by these components in malarious developing countries7-9. This side effect of malaria control with persistent insecticides has also received limited recognition from WHO.

French freedom

SIR — With reference to your important issue, Science in France (25 March), may I highlight one crucial advantage that French scientists enjoy over their British counterparts?

Applicants for a research grant, which may be rejected, have the statutory right of access, under France's freedom of information laws, to the case-file concerning their application, including referees' reports and other attendant reasons behind the decision, which they may then openly contest and indeed reverse¹.

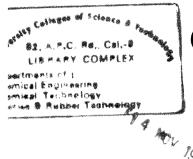

British scientists who feel that they order this matter better in France, compared, that is, with the closed and secretive system of administration in Britain, would do well to make strong representations to their MPs and trade unions ^{2,3}.

NEWS AND VIEWS

Geochemical light on mantle convection

from Donald L. Turcotte

Mantle convection is generally accepted to be the driving mechanism for continental drift and plate tectonics, but controversy persists about the scale on which the process takes place. Does convection involve the whole mantle, down to the boundary with the core? Or, as Allègre¹ has recently suggested on geochemical grounds, are only the upper layers of the mantle involved? Is there even, as Houseman and McKenzie² suggest, a second scale of mantle convection?

The controversy centres on the seismic discontinuity at a depth of 650 km, where seismic velocities increase by about 10 per cent. The increase can be attributed either to a solid-solid phase change or to a change of composition, perhaps of iron content. The absence of seismicity below this depth is taken as evidence that the convection associated with plate tectonics is limited to the upper mantle.

Geochemical observations lend further support to the notion of layered mantle convection. Systematic studies³⁻⁵ of isotopic ratios in the samariumneodymium system have shown that the upper mantle and the continental crust are complementary geochemical reservoirs. The upper mantle reservoir is systematically depleted in those elements, the rare earths for example, which are incompatible with the mantle material and the continental crust is correspondingly enriched. The mass balance of the Sm-Nd system suggests that 30± 10 per cent of the upper mantle has been involved, which is consistent with an upper mantle convection system limited to depths of less than 650 km.

A possible reservoir system is illustrated in the figure. Mid-ocean ridges, which randomly tap the upper mantle reservoir, usually yield mid-ocean ridge basalts which are similar in both major and trace element chemistry, showing that the upper mantle reservoir is well stirred. Volcanism associated with the subduction zones systematically transfers incompatible elements into the continental crust. The remainder of the subducted lithosphere, including the enriched oceanic crust and depleted mantle, must then be mixed into the upper mantle reservoir in order to provide the nearby uniform and depleted basalts found at mid-ocean ridges.

This simple two-reservoir model does not, however, explain all the geochemical observations. Ocean island basalts (for example, Hawaii) are not systematically depleted but exhibit a range of geochemical signatures, from depleted to enriched. One explanation is that ocean island basalts result from partial melting in a plume rising from an undepleted lower mantle reservoir6, in which case the range of compositions is attributed to mixing between materials of the depleted upper mantle and the undepleted lower mantle. This model does not, however, explain all enrichments of ocean island basalts. whence the proposal⁷⁻⁹ that the source of the ocean island basalts is subducted oceanic crust, enriched with continental trace elements by seawater alteration and by the entrainment of sea-floor sediments10, that has not been fully mixed into the mantle.

In passing, the two-reservoir model must

also be amended to take into account the discordance between geochemical studies of the Sm-Nd system on the one hand and the strontium-rubidium and uranium-lead systems on the other. Fractionation within the crust seems to have depleted its upper layers of lead and strontium, suggesting a differentiation of the crustal reservoir into two. Whether the 'missing' lead is in the lower crustal reservoir or (as sulphide) in the molten core is disputed.

While these geochemical studies favour a layered mantle convection system, there are some difficulties. Thus Jordan and Creager¹¹ have suggested that travel time anomalies indicate the penetration of the descending surface plate to depths of at least 900 km, which argues against stratified convection.

If indeed the mantle is chemically stratified at 650 km or thereabouts, independent convection systems would be expected in the upper and lower mantle. If the observed discontinuity marks a phase change, its thermal coupling between the two systems will depend on the thermodynamic properties of the phase change. High-pressure measurements 12 using diamond cells with laser heating indicate that the principal upper mantle mineral olivine transforms to basic oxides (magnesiowustite plus perovskite) at conditions reasonably close to those at a

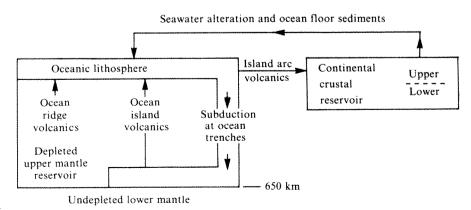

Illustration of the mantle reservoirs.

Donald L. Turcotte is Chairman of the Department of Geological Sciences at Cornell University, Ithaca, New York 14853.

depth of 650 km, but not enough is known about this transformation to decide whether it would assist or block convection. Moreover, Liu¹³ argues that there is a significant discrepancy between predicted and required conditions for the olivine transformation, and favours chemical stratification.

Further objections have been suggested by the laboratory and numerical studies of stratified convection carried out by Richter and McKenzie¹⁴, who predict a double thermal boundary layer at the interface between the convecting layers with a significant increase of temperature across it. But this increase of temperature would imply¹⁵ a large (several orders of magnitude) decrease in viscosity which is not consistent with observation of postglacial rebound. This conclusion is a serious difficulty for the concept of stratified convection which is unlikely to be recovered by a consideration of dependence of the viscosity or rheological differences between the convecting layers.

That there may be a second and smaller scale of mantle convection is suggested by several observations. One is intraplate volcanism, such as that at Hawaii and other oceanic islands. Another is the requirement that the upper mantle reservoir be well stirred or mixed in order to have a nearly uniform composition. Richter and Parsons¹⁶ suggested that instabilities within the lithosphere may be responsible, but Yuen, Peltier and Schubert¹⁷ have questioned the validity of the numerical

studies so far made of this process² on the grounds that they do not allow for the strong temperature dependence of the mantle viscosity. They go on to suggest that the hot, low-viscosity lower boundary layers are more likely to be unstable than the lithosphere. And, such unstable lower boundary layers could help them to explain the ocean island volcanism.

It is, of course, too soon to known how these questions will be decided. What is, however, already plain is that geochemical methods will throw light on the mechanisms of mantle convection, which are not merely the driving forces of continental drift but powerful agents in the evolution of the planet.

Parental mutagenesis and familial cancer

from H.J. Evans

PEOPLE can inherit mutations which predispose their offspring to the early development of specific cancers, and which are loosely referred to as 'cancer genes'1; and mutagen-induced chromosomal rearrangements, or more subtle mutations, may initiate malignant transformation in exposed somatic cells². Does this mean that exposure to mutagenic carcinogens results not only in an increased incidence of cancer in exposed individuals, but also in their descendants?

It is recognized that abdominal exposure of pregnant women to X-rays may result in an increased incidence of leukaemia in the resultant offspring⁴; that maternal exposure to synthetic oestrogens during pregnancy can result in the subsequent development of vaginal adenocarcinoma in female children⁵; and that exposure of children to asbestos dust brought home from the work place by an occupationally exposed parent is responsible for the later developmental of mesothelioma in exposed offspring⁶. More recently, an excess of

brain tumours has been noted in children of adults occupationally exposed to chemical solvents⁷. But in all these studies, the excess cancers are the result of the exposure of the offspring themselves and are not a consequence of gonadal exposure of parents and transmission of a cancerpredisposing genotype to the offspring. Indeed, the evidence in man for transmission of any kind of induced germ cell mutations to offspring by parents exposed to chemical mutagens is almost nonexistent, with some limited evidence from studies of individuals exposed to vinyl chloride8 or to anaesthetic gases9,10. There is no information available on any possible germ cell transmission of an acquired cancer risk from parent to offspring. What evidence do we have from experimental

H.J. Evans is Director of the MRC Clinical and Population Cytogenetics Unit, Western General Hospital, Crewe Road, Edinburgh EH4 2XJ. studies on animals?

Following the original report of transplacental carcinogenesis in pregnant female mice exposed to urethane¹¹, there have been a number of studies on tumour incidence in offspring of pregnant animals exposed to chemical mutagenic carcinogens. In some cases, inbred lines of mice12 or rats13 have been used and brother-sister matings followed through to the F₂ or F₃ generations. All reports show that treatments that result in tumours in exposed individuals and their immediate descendants also result in an excess of tumours in F₂ and F₃ animals. That the enhanced tumour incidence in later generations is not due to transmission of the carcinogen through mother's milk or excreta was ruled out through the use of rapidly metabolised and inactivated mutagens such as N-nitrosomethylurea (NMU)¹³ or N-nitrosoethylurea (ENU)¹⁴. Moreover, in a recent study, Tomatis et al. 15 have shown a similar increased incidence of tumours in F₁ offspring of male rats treated with ENU some weeks before mating, so that a mutagen-induced enhancement of tumour incidence can also be transmitted through the male germ line. The story is taken further by the large-scale study reported by Nomura in this week's Nature in which tumour incidence in offspring of male and female mice exposed to X rays or urethane has been followed over a number of generations.

On page 575, Nomura summarizes a study extending over ten years, and involving some 15,000 mice, and reports that exposure of late-stage male or female germ cells to X rays gives a linear increase in dominant lethals with dose, but no increase when animals are exposed to the mutagen urethane; however, parental exposure to both agents resulted in congenital abnormalities in F₁ embryos. Of special interest is the finding that both X-irradiated and urethane-treated male or female mice produced progeny with a much increased tumour incidence, with a clear doseresponse relationship for offspring derived from irradiated late-stage germ cells. At the highest X-ray dose of 500 rads, the tumour incidence in the offspring of irradiated animals (~30 per cent) was some six times that in the controls (5 per cent). The spectrum of tumours in controls and in offspring of treated parents was similar, with some 90 per cent being non-malignant papillary adenomas of the lung and the remainder various malignant tumours of other organs. Matings continued down to the F₃ generation clearly demonstrated heritability of the induced high tumour incidence and the pattern of inheritance is that of a dominant trait with 40 per cent penetrance. Although the X-irradiation of males resulted in dominant lethals and cytologically demonstrable translocations, no such effects were observed in animals treated with urethane, and Nomura argues that the mutations that result in excess tumours are probably not gross

chromosomal rearrangements.

The rate of X-ray induction of mutations that predispose to tumour development turns out to be around ten times greater than the mutations that, for example, result in skeletal changes in the mouse and Nomura suggests that there may be a large number of sites in the genome where mutation may predispose to tumour development. Other explanations are possible, but whatever mechanism is involved it is clear that mutagen exposure results in transmitted heritable changes that considerably enhance tumour incidence in the offspring. The demonstration of this effect required parental exposure to fairly high doses of mutagens and the use of inbred lines and we may ask whether these results are of significance in relation to human exposure to mutagens. There is no reason to believe that effects similar to those in the mouse may not occur in man, although they would be less easily demonstrated. In this context, two human populations of interest would be the offspring of the survivors of Hiroshima and Nagasaki who were exposed to high radiation doses, and who showed an enhanced cancer incidence and chromosome damage in their blood cells 16, and the offspring of cigarette smokers who must comprise one of the largest groups of individuals exposed to a chemical mutagen at dose levels sufficient to produce significant chromosome damage in their blood lymphocytes 17.

With increasing molecular size, however, new problems arise. First, there is the inability to resolve the resonances; increasing molecular weight increases not only the number of resonances but also their peak width. With hundreds or even thousands of proton resonances spread over a frequency range of only a few kilohertz, considerable overlap is inevitable. Even with resonances that can be resolved, an even greater problem is presented by their assignment. Not all the factors affecting chemical shift can be analysed exactly, so that a peak at a given frequency can only be definitely assigned to its corresponding nucleus by direct experiment. This often means chemical modification of the molecules, or comparison of almost-identical proteins, and the labour required for even one or two positive assignments in the spectrum of a protein can be enormous. Once assigned, however, the chemical shift, splitting and other features of the resonance can provide sufficient information about its local chemical environment, including dynamic behaviour, to make the effort well worthwhile.

The work presented by Wuthrich et al. represents the culmination of several years of development, in their laboratory and others (notably that of Ernst), of new NMR techniques which not only provide solutions to the problems of resolution and assignment, but further point to a scheme for the determination of protein structure in three dimensions directly from NMR experiments. The methods are those of two-dimensional NMR, in which the sample is subjected to a sequence of radiofrequency pulses of the general form 'pulse-evolution time t_1 - pulse - data acquisition time t2'. The data are thus collected as a function of t_2 with t_1 as a parameter, and if a large number of experiments are perforned for different values of t_1 the result is a matrix of data points, each of which is a function of both t_1 and t_2 . This matrix is Fourier-

New dimensions in protein NMR

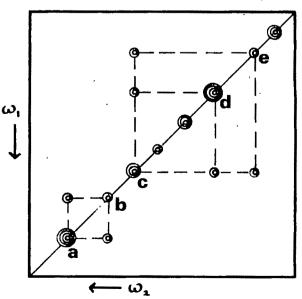

from H. W. E. Rattle

NUCLEAR magnetic resonance (NMR) has been much in the news of late; the obvious biochemical and medical applications of such techniques as topical magnetic resonance (TMR) and NMR scanning have aroused a great deal of interest. Arguably, though, an even greater revolution has been going on in the application of NMR to the determination of the molecular structure of proteins, and a recent sequence of papers14 from Wüthrich and his colleagues shows clearly that it may soon be possible to derive structural information from peptides and the smaller proteins in solution at the same levels of resolution as we have become accustomed to seeing from X-ray crystallography.

When the first protein samples were put into 40 and 60 MHz NMR spectrometers in the mid 1960s, they produced a spectrum of three or four broad featureless humps which made it clear that much work would be needed before useful information could be obtained. The advance of high-field magnet technology produced great improvements, as did the rapid data acquisition made possible by the Fourier transform method. The nuclear spins of the sample are perturbed by the application

of a radio-frequency pulse, and their subsequent collective behaviour monitored as a function of time. Fourier transformation of the resulting amplitude—time function produces the NMR spectrum with each resonant nucleus in the molecule giving rise to a peak at a position on a frequency scale (the chemical shift) which depends on its precise environment within the molecule.

Schematic representation of a two-dimensional COSY or NOESY contour-map spectrum. The peaks of the conventional proton magnetic resonance spectrum appear along the diagonal, and crosspeaks reveal the connectivity between resonances a and b, and between c, d and e. (Adapted from ref.5.)

H.W.E. Rattle is in the Biophysics Group at Portsmouth Polytechnic, St Michael's Building, White Swan Road, Portsmouth POI 2DT, UK.

transformed twice to yield a twodimensional spectrum in which peaks appear as functions of two frequencies ω_1 and ω_2 . In the presentation favoured by Wüthrich et al., the spectrum is plotted as a square contour map with the peaks of the conventional spectrum appearing along a diagonal. Clearly more data can be presented in two dimensions than in one. but the real advantage goes far beyond this. By the selection of pulse sequences and appropriate values for the evolution time, each pair of nuclei which interacts within the molecule is made to reveal its 'connectivity' by the appearance of an offdiagonal peak (a cross-peak) on the spectrum. The connectivities may be through-bond spin-spin couplings (J-couplings), in which case the technique is termed two dimensional-correlated spectroscopy (COSY), or across-space connectivities produced at ranges of up to a few Angstrom units by the nuclear Overhauser effect (NOESY) (see the figure). Since nuclear Overhauser effects vary with distance, it should eventually be possible to measure short internuclear distances between nuclei not directly linked by bonds; for which at present only approximate values are obtainable.

The general scheme for using COSY and NOESY proton spectra is then as follows: spectra are obtained from a peptide of known sequence in aqueous (H2O) solution, and at least one backbone a-CH or N-H resonance assigned by conventional means. Spin coupling of this resonance to those of adjacent residues along the chain produces cross-peaks, thus permitting assignment of peaks from the neighbouring residues. These in turn have cross-peaks with the next residues, and so the whole protein backbone may be assigned sequentially. Across-space NOE connectivities obtained from the NOESY spectrum add to and confirm the assignments; detailed analysis of known protein structures show that between 70 and 95 per cent of close approaches are between contiguous residues. Virtually complete assignments of every proton in the molecules of basic pancreatic trypsin inhibitor (58 residues) and membranebound glucagon (29 residues) are presented as proof of the efficacy of the method. Given such full spectral assignments, an even more interesting prospect appears, since NOESY spectra can give at least semiquantitative values for the distances between the α -CH proton of the *i*th residue and the backbone NH proton of the (i+1)th, between backbone NH protons of adjacent residues, and between B-CH or β -CH₂ of residue *i* and NH of residue (i+1). The conformation of a residue is as completely specified by these distances as it is by the more conventional Ramachandran bond angles ψ , ϕ and χ . Given enough NOESY measurements of such distances, even if only approximate, and using the other known constraints on the folding of the protein, it should be possible

with appropriate computer methods to arrive at a fairly complete determination of protein conformations in non-crystalline environments, at least for proteins smaller than 70-100 residues. Of course COSY, NOESY and other two-dimensional NMR methods may also be used in conjunction with the many valuable conventional methods, such as paramagnetic probes, relaxation measurements, biochemical modifications and others which are already in regular use. The instrumental requirements for two-dimensional NMR are considerable: high spectrometer

frequencies (300-500 MHz) coupled with computing facilities capable of handling a two-dimensional spectrum which may be the equivalent of several hundred conventional spectra. The advances made possible, however, are very considerable.

The big bang — 'free lunch' at the Royal Society

from Craig Hogan

COSMOLOGISTS seem to have spent a great deal of time over the years talking about the same things over and over again: element abundances, background radiation, galaxy formation and the like. In so doing they tend to oscillate between congratulating themselves on how much they think they understand and despairing that they will never know anything for certain. Both of these moods were much in evidence at a discussion meeting held recently at the Royal Society, supposedly on "The Big Bang and Element Creation" but actually covering a wide range of subjects intended to span the whole range of observational cosmology and a good deal of theoretical cosmology.

As expected, the most genuinely new results came from groups measuring anisotropy in the microwave background radiation. D.T. Wilkinson (University of Sussex), whose experiment is capable of measuring large-scale (90°) angular fluctuations in radiation temperature with a system noise of only 0.1 mK (compared with the total 3K background temperature), described a possible observation of a cosmological quadrupole moment with amplitude $\delta T/T \simeq 10^{-4}$ which, if true, would be an observation of historic significance, because such measurements observe structural properties of the Universe at very early times, possibly even the big bang itself. Unfortunately, as Wilkinson noted, such observations are beset with numerous systematic difficulties expected to be only slightly fainter than the observed signal, and this became obvious when he showed a sky map made with a new low-noise maser detector in which the Galaxy appeared as a bright band that was much more conspicuous than any trend in background brightness. R. Fabbri (University of Florence) described results from the

Craig Hogan is in the Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge CB3 0HA. Florence group and cited tentative evidence that cosmological fluctuations at 6° angular scale are smaller than the quadrupole ($\delta T/T = 3 \times 10^{-5}$) and decreasing with angle — a result as exciting as Wilkinson's, but difficult to reconcile with it in any simple picture. On the other hand, Wilkinson showed very clearly that the dipole moment ('the great cosine in the sky' due to the Earth's motion) is now firmly established, even if minor differences still exist between various groups.

In the same tone, P.L. Richards (University of California, Berkeley) showed that the spectrum of the background radiation is indeed very nearly blackbody down to submillimetre wavelengths, even though controversial apparent departures from an exact thermal spectrum may exceed the statistical limits. Woody and Richards' technological achievement may be appreciated by noting that the cosmological background they measure had a brightness only 10-5 of an ordinary body at room temperature. New experiments were described which may check the significance of the spectral distortion, which again, if real, gives us significant positive information about the early evolution of the Universe.

Measurements of the cosmic abundance of the elements - to date, the only independent verification that the microwave background is primordial were reviewed by B. Pagel (Royal Greenwich Observatory). Progress has been made here too, with the best measurements (optical observations of HII regions) of primordial helium abundance by mass giving $Y_p \sim 0.23 \pm 0.01$, a conservative statement being $Y_p < 0.25$. As pointed out by D. Schramm (Enrico-Fermi Institute, University of Chicago), with $Y_{\rm p} = 0.25$ the hot big bang predicts the observed abundances for deuterium and ³He with remarkable success.

However, the helium observations now

also place serious constraints on the standard hot big bang model. M. Davis (Center for Astrophysics, Cambridge, Massachusetts) showed evidence from the flow of galaxies in the Virgo supercluster that the total mass density of the Universe is at least one-fifth of the density which would be necessary to keep it from expanding forever in terms of the conventional cosmological density parameter, $\Omega_{TOTAL} >> 0.2$. Most of this mass is dark material whose nature is unknown. If, however, it were made of ordinary matter, the hot big bang predicts that the amount of helium produced would exceed the observed limits. If the standard model of helium synthesis is correct, then $Y_{\rm p}$ < 0.25 implies that the fraction of closure density in baryons is $\Omega_{\rm B}$ < 0.1. Therefore, the standard model already requires that most of the mass in the Universe is some other form of matter for example, massive neutrinos, or black holes which formed before nucleosynthesis, or something even more exotic. As Schramm pointed out, the standard model would be ruled out altogether if Y_p proved to be less than Pagel's 'best' value of 0.23. In view of this sensitivity, the success of the theory must be regarded as even more remarkable.

W. Sargent (Caltech) pointed out that deuterium may appear in high-resolution spectra of very distant objects — the Lyman- α absorption due to hydrogen clouds in front of high-redshift quasars. Such systems provide direct, if fragmentary, information about the intergalactic gas at redshift of order 2, and have already been used by Sargent and his collaborators as a probe of galaxy formation processes.

The simplest prediction of all was made by A. Guth (MIT), who showed that in some circumstances, a tiny region (or 'bubble') of primeval vacuum could inflate to include the entire observable universe, then decay to fill it with all of the matter and radiation.

The reason such a scheme is possible in the context of modern gauge theories is that the primordial vacuum is allowed to have a large energy density. When such a 'false' vacuum expands, its energy density does not decrease (like ordinary matter) but stays the same, which enables the universe to expand by a very large factor while remaining at the same density. The universe becomes 'normal' when the energy of the vacuum is converted into ordinary matter and radiation (by a decay process which is not well understood, and which is the focus of research), and the vacuum becomes the normal, nongravitating 'true' vacuum we have today. (We know that the energy density of the present-day vacuum is nearly zero because the 'cosmological constant', which measures its effect on the present-day expansion, is shown by observations of distant galaxies to be nearly zero.)

Such an 'inflationary universe' auto-

matically predicts that $\Omega_{TOTAL} = 1 \pm \epsilon$ (where $\varepsilon << 1$), and, because of the uniformity of the vacuum, also predicts that no primordial fluctuations are produced — the early Universe is both very flat and very uniform. It appears that in this kind of scheme, one will have to find an explanation for the observed nonuniformity in terms of processes occurring after the inflation. However, the most interesting of Guth's speculations is that the bubble of vacuum, and hence the entire universe, could arise by quantum fluctuation 'from nothing'. Apparently certain kinds of gauge symmetry might predict not only the structure of matter but also the structure and existence of the space time in which the matter fields operate.

Nowadays, not only does modern physics give you electrons and atoms, but it also gives you universes. Guth's vision of the Universe as a 'free lunch' will appeal to many. I walked away afterwards (as it turned out, to go to lunch) feeling perplexed as if by a koan — if the Universe owes its existence and symmetry to gauge theory, does the gauge theory owe its 'realization', and hence its existence or 'reality', to the Universe it creates? No doubt these speculations will provide cosmologists with plenty of food for thought.

When is a zeolite not a zeolite?

from Lovat V.C. Rees

In 1972 the Mobil Oil Corporation synthesized and patented a range of very high Si/Al zeolites of which ZSM-5 is the best known example. This zeolite is a catalyst of great importance in the synthesis of petrol from coal (see Thomas et al., this issue of Nature p.530) and the Mobil patent is thus of considerable commercial significance. As Thomas et al. indicate, the Union Carbide Corporation has more recently synthesized and patented a new, thermally stable, crystalline phase of silica, called silicalite, which is topologically very similar, if not identical, to ZSM-5.

Silicalite, however, always contains some aluminium (Si/Al ratios >200 are usually found) which Union Carbide assert is present in the form of Al₂O₃ impurity. The Mobil patent for ZSM-5 embraces Si/Al ratios of up to 4,000, so the zeolite may contain less aluminium than some samples of the silicalite. If some of the aluminium in silicalite is present as tetrahedral framework aluminium, then a philosophical argument arises as to whether a sample of ZSM-5 (US Patent 3702886, 1972) with very low aluminium content is in any way different from silicalite (US Patent 4061724, 1977). This philosophical argument, which could have considerable financial implications, can be carried a stage further when one asks "When is a zeolite not a zeolite but a defect silica"?

If the aluminium content decreases below one aluminium atom per unit cell, can we still consider the material to be an aluminosilicate with a specific unit cell formula or is it a defective form of crystalline silica? Even if one aluminium per unit cell is present, if this aluminium atom is randomly distributed among all tetrahedral sites in the unit cell is this material

Lovat V.C. Rees is Reader in Physical Chemistry at the Imperial College of Science and Technology, London SW7 2AY. any more a zeolite than material containing less than one aluminium per unit cell?

The paper from Thomas and his colleagues at Cambridge and Guelph goes to the heart of this question. They have shown by ²⁷ Al magic-angle spinning NMR (MASNMR) that all of the aluminium atoms in a very 'pure' silicalite (Si/Al>1,000) and the less 'pure' commercial silicalite (Si/Al>200) are located in tetrahedral sites. No noctahedral aluminium was detected. They also found a small signal in their 29Si MASNMR spectrum of the commercial silicalite due to Si(1Al) which must be present if the aluminium is present in tetrahedral coordination. If these results are accepted then we must draw the conclusion that silicalite is essentially indistinguishable from a high Si/Al ratio ZSM-5 and leave the question of whether these materials are

Zeolites are crystalline aluminosilicates which are widely distributed in nature but are also readily synthesized in the laboratory. The general formula for a zeolite may be written as:

 $M_{x/n} [(A1 O_2)_x (Si O_2)_y] mH_2O$

where M is a cation of valency n and the Si/Al ratio can range from one to very large values. In many zeolites, the zeolitic water can be readily removed without lattice collapse, leaving a porous crystal with void volumes which can be as large as 50 per cent of the crystal volume. This void volume consists of a network (frequently three-dimensional and interconnected) of channels of molecular dimensions. Zeolites have found wide use, therefore, as molecular sieves and as acid catalysts. When the M cations are replaced by H+ ions, very active cracking, hydrocracking and isomerization catalysts are produced which are extensively used by the petroleum industry.

zeolites or not unanswered.

Another novel application of 29Si and ²⁷Al MASNMR, and some further exciting results, are presented in this issue in a second, joint contribution from the above two schools (see p.533). Zeolite Y (synthetic faujasite) as synthesized is an excellent cracking catalyst but is found to be inadequate under plant use when high temperatures are employed in the decoking. process. The conversion of zeolite Y to an ultra-stable form was an important development which has led to the production of >200,000 tons of ultrastable zeolites per annum. Although the

main features of this stabilization process have been indicated in previous publications, the new work presents convincing evidence of the fate of the aluminium atoms removed from tetrahedral framework sites and of the healing of the vacancies so produced by silicon atoms which come, not exclusively from surface or amorphous regions of the crystal, but also from the bulk crystal. A direct probe has been brought to bear, therefore, to monitor the internal reorganization of tetrahedral atoms which converts a catalyst into a commercially viable catalyst.

What next will we find by MASNMR? \Box

Much of the best evidence comes from platelets, where receptor-coupled disappearance of PI almost certainly involves the activity of a phosphodiesterase (a phospholipase C), whilst Ca2+-mediated PI disappearance is caused by an acylhydrolase (a phospholipase A)9,10. Only the former is of any immediate interest when considering the possible coupling function of receptor-controlled breakdown of inositol lipids. Neither the experiments of Farese¹¹ on pancreas nor of Cockcroft¹² on leukocytes demonstrate the route of Ca2+-dependent PI 'breakdown' in receptor-stimulated cells.

Hawthorne correctly points out that the data on bovine adrenal medulla are not easily reconciled with the inositol lipid breakdown/Ca²⁺ mobilization hypothesis. Additional information on this system should be illuminating.

It has generally been considered that inositol lipid metabolism is stimulated by activation of muscarinic cholinergic receptors at both pre- and postsynaptic sites, and Hawthorne states this view as a fact. Recent work, however, has shown that in 'synaptosomal' fractions at least a proportion of this response is associated with postsynaptic elements¹³, and I¹⁴ have offered additional arguments to suggest that there may be no presynaptic stimulation of PI metabolism by muscarinic cholinergic stimuli. If this were to prove the case, then the failure of presynaptic muscarinic receptors to mobilize Ca2+ would tally well with their failure to stimulate inositol lipid metabolism.

Hawthorne states that "there are so many systems in which the receptor-linked PI loss requires external Ca2+ that a universal role of PI in Ca2+ mobilization cannot be upheld". This statement is fundamentally flawed, since it fails to recognize that a requirement for extracellular Ca2+ does not constitute proof that a change in cytosol Ca2+ concentration controls PI breakdown (see ref. 8 for a detailed discussion).

For the past few years it has been generally held that the first lipid to break down in stimulated cells is PI rather than one of its phosphorylated derivatives,

Is phosphatidylinositol really out of the calcium gate?

from Robert H. Michell

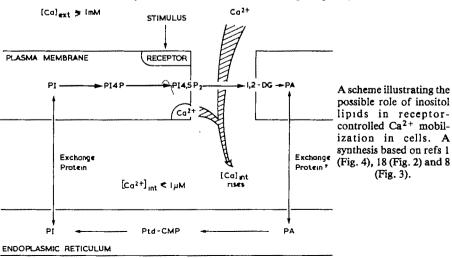

Seven years ago I suggested that receptorstimulated breakdown of phosphatidylinositol (PI) might be implicated in a general mechanism whereby activation of many cell-surface receptors brings about a rise in the cytosolic Ca2+ concentration in stimulated cells1. In recent months, two brief reviews, one by J.N. Hawthorne in these columns, have argued that this general hypothesis is no longer tenable^{2,3}. .By contrast, a number of other recent reviewers have continued to treat it as a useful working hypothesis, despite emphasizing that it is still unproved4-8. I would like briefly to summarize some of the weaknesses of Hawthorne's recent News and Views article3. I feel that these criticisms are sufficiently fundamental to raise serious doubts about the purported disproof of the postulated link between stimulated inositol lipid breakdown and the mobilization of Ca2+ in stimulated cells.

Hawthorne considers that the proposed mechanism for Ca2+ mobilization is cumbersome, mainly because not all the necessary enzymes are at a single cellular site, and that it is wasteful of energy. But membrane lipids are always in a state of continuous metabolic turnover, and the rapid synthesis to support this continuous turnover occurs mainly at the endoplasmic reticulum. The inositol lipids of the plasma membrane that are involved in cell responsiveness may simply be renewed by intracellular synthesis rather more rapidly than the other phospholipids of the plasma membrane. When considering how much energy this costs, a comparison with adenylate cyclase may be instructive. Synthesis of cyclic AMP expends two highenergy phosphate bonds (plus an unquantified consumption of GTP by the guanyl nucleotide-binding coupling protein) and yields a single molecule of the intracellular

Robert H. Michell is Senior Lecturer in the Department of Biochemistry, University of Birmingham, PO Box 363, Birmingham B15

messenger. Breakdown and resynthesis of one molecule of PI consumés three highenergy phosphates (assuming conservation and reutilization of the diacylglycerol mojety). If the intiating event turns out to be phosphodiesterase attack on PI 4.5-bisphosphate (PI4,5P₂; see below), then this expenditure will rise to five highenergy phosphate bonds. As a result of this breakdown, we can assume the release of some membrane-bound Ca2+ and/or the opening of a Ca² channel. Thus the breakdown of one lipid molecule might allow the mobilization of many Ca2+ ions into the cytosol compartment of the cell. The three (or five) phosphate bonds seem likely to be a minor energetic consideration, since most energy expenditure during Ca2+ signalling undoubtedly occurs in the maintenance of the large Ca2+ gradient at the plasma membrane by continuous pumping of Ca2+ out of the cells, rather than in the control of Ca2+ re-entry.

As Hawthorne mentions, there are situations in which the admission of Ca2+ to cells, either by receptor activation or by using an ionophore, can cause the disappearance of PI, but in no case has the route of breakdown been fully documented.

possible role of inositol lipids in receptorcontrolled Ca2+ mobilization in cells. A synthesis based on refs 1 (Fig. 4), 18 (Fig. 2) and 8 (Fig. 3).

PI4P and PI4,5P2. Breakdown of either one or both derivatives was only reported in conditions likely to raise cytosol Ca2+ concentrations greatly, and studies of the enzyme responsible for their Ca2+mediated breakdown in red cells indicated that this enzyme is very unlikely ever to be controlled by Ca2+ in healthy cells15. Recent studies of liver and parotid cells have, however, revealed a second type of PI4,5P, breakdown that is very rapid, closely coupled to receptor occupation and not Ca2+-mediated (refs 8, 16, 17 and unpublished data of L.M. Jones and C.P. Downes). This raises the novel possibility that the initiating reaction in Ca2+ mobilization is receptor-controlled breakdown of PI4,5P2, a characteristic lipid of the plasma membrane, and that the disappearance (that is, apparent 'breakdown') of PI so far studied is really a reflection of the consumption of PI during resynthesis of degraded PI4,5P₂. This does not constitute any fundamental change to the original view that the widely observed 'PI response' is somehow essential to Ca2+ mobilization by receptors, rather it acknowledges our increasing knowledge of the mechanism of this response: originally we had to discuss the function of stimulated PI and phosphatidate labelling, later we were able to focus on PI 'breakdown', and investigation of receptor-controlled PI4,5P, breakdown may now take us one step closer to a final understanding of this long-standing puzzle. The figure shows our current working hypothesis.

In no sense should the information that appears to link breakdown of PI4,5P₂ (or PI) to the mobilization of Ca²⁺ in stimulated cells be taken as conclusive proof of this link. We are still much too ignorant of the details of the processes to draw any such conclusion. Equally, however, I consider that the evidence marshalled as a purported disproof of this hypothesis is far less convincing than Hawthorne³ and Cockcroft² would have us believe. Let us not reject this working hypothesis prematurely.

X-chromosome inactivation and the control of gene expression

from Martin H. Johnson

WHAT is the relationship between the state of chromatin and the expression of genes? The heterochromatic and inactive X-chromosome appears to offer an appealing model system to tackle this question, since during X-inactivation (or reactivation) the alteration of potential genetic activity, and its inheritance through many cell generations, involves simultaneous changes to a large and coherent group of genes rather than to a series of genes scattered throughout the genome. During the course of a recent meeting in Bangalore*, it became clear that this assumption was too simple. It emerged that the condensation of the X-chromosome, and indeed of heterochromatin elsewhere in the genome, may be a secondary phenomenon, perhaps related primarily to the evolution of sex, and that the selective activity of genes during differentiation might be regulated by other mechanisms altogether.

In the eutherian mammal, the embryo begins life with two active X-chromosomes, but the paternally derived one is later inactivated in trophectodermal and primary endodermal cells (N. Takagi, University of Hokkaido). The cells resemble those cell lineages in adult marsupials in which the paternal X-chromosome is inactive (it is partially active in some lineages), although it is not clear whether this is a result of failure to activate the paternal X-chromosome at fertilization, or of activation followed by preferential inactivation (J. Graves, LaTrobe University). An impressive array of cytogenetic, biochemical and embryological evidence suggests that, in the primary ectoderm (epiblast) of eutherian mammals, random rather than selective inactivation of the X-chromosome occurs between 51/2 and 61/2 days (Takagi; M. Monk, MRC Mammalian Development Unit, London; M. Lyon, MRC Radiobiology Unit, Harwell).

The simultaneous occurrence of X-inactivation, whether random or paternal and in embryo or embryonal carcinoma cell (Takagi), and the generation of differentiated cells from a stem cell population, lead Monk to propose that both arise from a single genetic change. She suggests that X-inactivation may be just one part of a more general process of genetic determination and that both events might be mediated by the same molecular mechanism. Experiments in which X-inactivation is reversed complicate this simple but attractive idea.

Three types of reversal were described. First, A. McLaren (MRC Mammalian Development Unit, London) presented evidence that the germ cells, although stem cells, had an inactive X-chromosome during their mitotic proliferation in the primitive mouse gonad of 111/2 days gestation. Biochemical, genetic and morphological evidence showed clearly that between 12½ and 13½ days both X-chromosomes became active at some point before entry into prophase of the first meiotic division. Second, T. Mohandas (University of California, Los Angeles) exposed mouse-human cell hybrids (Science 211, 393; 1981), in which the human locus for hypoxanthine phosphoribosyltransferase (hprt+) was on an inactive X-chromosome, to 5-azacytidine, an agent known to reduce DNA methylation (see below), and selected in HAT medium. Clones of hybrid cells, in which human HPRT activity was stably expressed for over six months in culture, were generated and extracted DNA was shown to transform HPRT-negative cells. Graves similarly found that 5-azacytidine treatment of an F, cell line derived from a hybrid Mus musculus × M. caroli (in HPRT-deficient clones of which the M. caroli X-chromosome was inactive) resulted in stable re-expression of the M. caroli form of HPRT. Loss of HPRT activity in thioguanine-resistant revertants accompanied loss of the M. caroli X-chromosome, confirming that the reactivated locus was still on the X-chromosome. In six per cent of reactivant clones, the M. caroli form of glucose 6-phosphate dehydrogenase (G6PD) was also expressed, suggesting that reactivation events at the two loci were not independent.

Finally, Graves described experiments in which the hprt+ locus on the inactive M. caroli X-chromosome was reactivated simply by cell hybridization, either with undifferentiated embryonal carcinoma stem cells or with male-derived mouse or Chinese hamster fibroblasts. Again, the loss of HPRT activity in segregants was concordant with loss of the M. caroli X-chromosome. The reactivation frequency induced by fusion was much lower than that induced by 5-azacytidine. Recently, de Jonge et al. (Nature 295, 624; 1982) have also reported reactivation of the inactive human hprt + gene independent of 5-azacytidine treatment; DNA from human cells carrying an inactive hprt+ locus was used to transform HPRT-

Martin H. Johnson is in the Department of Anatomy, Downing Street, Cambridge CB2

^{*}The conference on "Condensed Chromatin and the Human X-Chromosome" was organized by H. Sharat Chandra at the Indian Institute of Science, Bangalore, India, 14-16 December 1981.

negative mouse fibroblasts and expression of the hprt+ gene was detected.

In experiments involving reactivation either by 5-azacytidine or by cell hybridization, the inactive X-chromosome remained heterochromatic and allocyclic. Although HPRT activity was being selected for, G6PD and phosphoglucokinase activities were also expressed, but only occasionally. A selective reactivation of discrete loci thus seems to have occurred — a process quite distinct from the natural reactivation described by McLaren in which the entire X-chromosome ceases to be heterochromatic and expression of any or all loci can occur. This selective reactivation is reminiscent of the continuing activity of X-linked loci Xg and Sts on otherwise inactive, allocyclic and heterochromatic X-chromosomes. The X-chromosomes may thus be inactivated at the level of individual genes (which can be switched on or off as can any developmental genes on autosomes) or at a higher level where the chance of individual genes switching on is reduced. The use of 5-azacytidine or cell fusion for reactivation may somehow selectively penetrate the higher-order suppression. That conclusion made it seem less likely that X-inactivation will prove to be a good model for studying the control of gene activity during development.

The capacity of 5-azacytidine to induce reactivation of X-linked loci is consistent with a model for X-inactivation first put forward in 1975. R. Holliday (National Institute for Medical Research, London) and A. Riggs (City of Hope Medical Center, Duarte, US) suggested that methylation of CpG sequences at replication would provide an inheritable change in the DNA that could be associated with suppression of activity and hence could also lead to X-inactivation. Suppression of methylation during one round of replication would generate hemimethylated strands which, on a second round of replication, would leave some cells carrying non-methylated sequences and other cells methylated sequences. Divergence of gene activity in different cell types could thus be achieved. Two rounds of DNA synthesis do indeed seem to be required between each determinative event during early mouse embryogenesis (M. Johnson, University of Cambridge).

Reactivation by 5-azacytidine may occur because it substitutes for cytidine but cannot itself be methylated. However, Jones and Taylor have observed that the extent of demethylation induced by 5-azacytidine is significantly greater than would be expected from substitution alone, and may thus involve a more generalized suppression of methylase activity. If demethylation by 5-azacytidine does occur on such a large scale, why is the whole X-chromosome not reactivated instead of just one or two loci? It seems clear that methylation changes are not in themselves adequate to explain the phenomena

observed — a conclusion supported by a recent report of Wolf and Migeon (Nature 295, 667; 1982). They compared the methylation patterns of DNA from cells with active or with active + inactive X-chromosomes by Southern blot analysis using cloned X-chromosome-specific probes and found no evidence to support any relationship between X-chromosome inactivity and degree or pattern of methylation.

Exciting news came from K. Jones (University of Edinburgh) who described a probe of approximately 200 base pairs, highly repeated, made to the minor density fraction of satellite DNA quantitatively associated with the W chromosomes of the banded krait, a snake in which the female is the heterogametic sex and the W chromosome is therefore equivalent to the Y chromosome of mammals. Remarkably, the Banded Krait Minor density fraction (BKM) probe also hybridizes to the W chromosomes of the females of a number of species of snakes, either at a single discrete area or at a series of sites along thechromosome; to bird W-chromosomes (female heterogametic); to regions tentatively indicated to be associated with the transposed and active mating-type locus (MAT) of yeast; and to the mouse (male heterogametic) Y-chromosome in the centromeric region. In addition, the probe bound to scattered sites elsewhere throughout the autosomes of mammals and also to mouse X-chromosomes carrying the 'Sxr gene'. The gene appears to be involved in primary sex determination as, when present in XX or XO mice, it causes a testis to be constructed. The origin of the Sxr locus has long been obscure, but Jones' demonstration that the highly conserved BKM target sequence is translocated from the Y-chromosome to the terminal arm of one X-chromatid during meiosis suggests that either the conserved

sequence, or more probably an associated flanking sequence, is the region coding for the sex-determining function of the Y-chromosome.

Jones suggests that this highly conserved sequence, in addition to its association with sex-determining loci, also defines functional domains in chromatin which are heterochromatic and allocyclic, as for example observed in the probe-positive region of the Y- and W-chromosomes, or is involved in the DNA conformational changes associated with conversion of yeast mating types from repressed to active states. The probe also hybridizes in the region of the proximal-most euchromatin (19A-D) and in the adjacent heterochromatin (19E-20B) of the Drosophila X-chromosome, a region proposed earlier in the meeting (D.L. Lindsley, University of California, San Diego) to be the site of sequences responsible for the precocious X-chromosome inactivation in the primary spermatocyte.

Jones proposed that the association of the highly conserved sequence with heterochromatic regions may have arisen in conjunction with the evolution of sex. If the sequence occurred on different primitive X-chromosomes to varying degrees, two classes of X-chromosome might develop. depending on the strength of the inactivating centres. The coincidence of strong centres on the chromosome carrying the putative sex-determining gene(s) could lead to genetic inactivity of the primitive X-chromosome at all times other than at the moment of determination of the male sex. Thus, most genes would rapidly be lost, generating a Y-(or W-) chromosome. With weak centres on the primitive X-chromosome lacking the sex-determining gene(s), activity would remain. On this basis, X-inactivation might be viewed simply as a relic of the requirement for a sex-determining chromosome.

100 years ago

THE ORIGIN OF THE SIGNS OF THE ZODIAC

THE origin of the signs of the zodiac is a question which we have but recently obtained materials for answering. Some of these symbols, certainly, are plain enough: it is not difficult, for instance, to discover the horns of the bull in the symbol of Taurus, or the arrow in that of Sagittarius. But the meaning of others, such as the symbols of Virgo, of Scorpio, or of Capricornus, is not so self evident. These symbols, however, are of comparatively modern invention, and first came into use along with the symbols still employed by astronomers to denote the planets. They cannot be traced further back than the tenth century, and owe their origin to the connection the alchemists believed to exist between the planets and the metals.

But modern though the symbols of the planets and zodiacal signs may be, it is quite otherwise with the signs themselves, and the majority of the names by which we still call them. Recent research has shown that the general voice of classical antiquity was right in regarding the Chaldeans as the first to map out the path of the sun during the year into separate regions, or constellations. Copies made by Assyrian scribes of older Babyloman works on astronomy have been found in the library of Nineveh, and are now in the British Museum.

It was the primitive population of Babylonia, now known by the name of Accadians, who first made Chaldea famous for its study of astronomy, and it is to them that the Signs of the Zodiac are due. Each sign represented a month of thirty days, and the signs and months were accordingly called by common names.

Some names clearly originated in the pecularities of the season when the sun was in a special sign of the zodiac. This is certainly the case with Aquarius, and it is probable that fish were particularly abundant under Pisces when the lowlands of Babylonia had been inundated by the rains.

SPRING BOOKS SUPPLEMENT

Where there's a need for some style

In science-writing it is hard to combine accuracy with fluency. Here Eric Ashby calls for more trouble to be taken over literary style in government reports.

In St Matthew's Gospel it is written: "Thou shalt love thy neighbour as thyself". A more recent writer puts it another way: "It is desirable that there should be established a meaningful and responsive reciprocal personal relationship within the social group". Here the choice between plain prose and jargon is easy to make. But some messages cannot be coded into words anyone can understand. Every issue of Nature carries pages that are meaningless except to a coterie of experts. This is not because the articles are badly written. It would be unreasonable to expect the author of an article on "Sub-GeV antiprotons in galactic cosmic rays" to make his message intelligible to anyone who can read a newspaper. He can assume that the few score of fellow experts for whom he is writing regard the content as almost all that matters in the article. He must avoid inaccuracy and ambiguity; fluency and elegance in style, though welcome and likely to enlarge the circle of readers, are of secondary importance.

The science-writer who chooses a wider readership has a more difficult task. No one is obliged to read what he writes. His motive—to communicate or maybe just to make money—will be defeated if he doesn't take trouble to set out his ideas in lucid, even if he can't manage limpid, prose. He has to adopt a style acceptable to the market place. This exposes him to certain temptations.

The chief temptation is to strive to be lucid at the cost of being accurate. How bracing it is to breathe the fresh air of Macaulay's prose: and how mistaken to suppose that science can be written in that style. It has been unkindly said about Macaulay's style of writing that you can never tell the truth in it. "In satisfying his passion for clarity" wrote the philosopher Brand Blanshard, "he allows himself to omit shades and qualifications that are there in the facts, but would smudge his sharply etched lines if he were to put them into the picture".

The science-writer with a passion for clarity has to take care that his passion does not lead him into infidelity to truth; for the reader who at first takes pleasure in the "sharply etched lines" may in the end feel resentment at having been deceived. That is what befell the American authors of The Limits to Growth. They arrest the reader's attention with a vivid scenario, such as the one that pollution, if it gets worse, may almost halve the expectation of life in industrial societies. They take no account of the fact that industrial societies react strongly to any threat to the expectation of life - as a dozen laws to abate hazards to health bear witness and the arresting scenario is in fact deceitful. It is commonly said that without the "sharply etched lines", the reader would not have taken the trouble to read the book at all. This is the dilemma, and the fact that so few writers can resolve it (and so many do not even try) provokes scientists to frown on a colleague who goes in for popularization; the word is so uncomfortably close to the French vulgariser. The rare writer who can successfully combine accuracy with fluency is not frowned upon: he is envied. But for most of us who write about science it is safer to settle for being painstaking about accuracy and be content with a modest measure of fluency.

However there is one category of science-writing where there needs to be a campaign for more fluency, even for elegance, in style: that is in the reports of scientific committees set up by government. The purpose of these reports is to help to shape science-policy. The committees that draft them take immense trouble to make them trustworthy. But — with some outstanding

exceptions — little trouble seems to be taken to make them attractive to read. The consequence is that some reports are read only by those whose duty compels them. And no wonder: listen (it's better to read them aloud) to a couple of examples taken at random from two important reports. Here is a paragraph from the recommendations of the Finneston Report, *Engineering our Future*:

All those involved with manufacturing industry, whether directly or indirectly, should review their activities to ensure that they perceive and present engineering and engineers as matters of vital national concern in their own right.

Does this mean: "The importance of engineers for industry and for the nation needs to be stressed"?

And here is a passage from the recommendations of the report on Global Resources to the President of the United States:

Because of the risk to peace, the United States should encourage other countries, and should itself, establish conflict resolution arrangements which can mitigate or help resolve future international water conflicts.

Does this mean: "There is an urgent need for ways to resolve conflicts over competing demands for water"?

There is no need for reports to governments to be written in this stilted and stumbling style. There are models of elegance on both sides of the Atlantic. The report, A Race against Time, by the Royal Commission on Electric Power Planning in Ontario, and the report by Mr Justice Berger on the Mackenzie Valley Pipeline (Northern Frontier, Northern Homeland), make compelling reading. These are both from Canada, where there is a higher level of literacy in government reports than in the USA. In Britain we have the example of an experiment in fluent writing with, so to speak, a "control" issued in the same year by the same government department. In 1970 the Ministry of Housing and Local Government issued two reports, one from the Technical Committee on the Disposal of Solid Toxic Wastes and one from the Working Party on Sewage Disposal. Neither of these topics is likely to inspire felicity in style, but the contrast between the two reports is striking. That on solid toxic wastes is pedestrian, the format dull, the readership correspondingly small. The report on sewage disposal was a pioneer in the attractive packaging of government reports. The photographs on the cover, the clever diagrams, the homely style, all these say to the reader: "This is not written just for civil servants: it is for you".

Stimulated by pressure groups and the media, the man-in-thestreet is becoming more and more concerned about technical decisions which affect his life. If he cannot participate in the decision-making (in public inquiries and the like) he at least wants to understand on what evidence the decisions are made. It is therefore a prime duty laid on those who write the reports of advisory committees and commissions to make them attractive and lucid enough to appeal to a much wider circle of readers than a handful of politicians and civil servants. It would be a public service if reviewers of such reports were to pay attention to style as well as content, praising good writing when they find it and censuring prolixity. Whitehead wrote that it is more important that a proposition be interesting than that it be true. Reports from scientific committees to governments need to be both interesting and true.

Heavenly insemination

Hugh Montefiore

I SUPPOSE that it is no more strange that an outstanding biologist such as Francis Crick should give his views on cosmology than that a distinguished astronomer such as Fred Hoyle should pronounce on molecular biology. To an outsider, these are both welcome pointers towards an integration of the sciences. So perhaps it was not outrageously odd to give Crick's book to a theologian for review; but he must walk warily on alien territory.

Crick writes ostensibly to answer Enrico Fermi's famous question, "If there are

intelligent beings in the galaxy, why aren't they here?", and he assesses the hypothesis known as Directed Panspermia, that is to say, a variant of Arrhenius's nineteenth-century theory, modified in that Crick considers whether life was deliberately planted on Earth. His book has nothing in common with Hoyle's views propounded in Evolution from Space (Dent, 1981). Crick. for example, does not seriously question whether the period needed for life to emerge by natural process requires a time span longer than the age of the Earth. Nonetheless he seems somewhat sensitive to his wife's criticism that his work may seem more like science fiction than a Nobel Prize winner's critique of a scientific theory. Perhaps for this reason Crick takes the opportunity (as his title suggests) to give his view on life itself, its origin and nature. Written with enviable simplicity and free of abstruse technicalities, it is as a result devoid of any annotation.

The answer that Crick gives to Enrico Fermi is that life on Earth could well have originated elsewhere in the Galaxy, and that there has been time enough for intelligent beings to evolve elsewhere in a suitable environment and to have despatched prokaryotic and eukaryotic microorganisms by rocket to this planet, whence life here may have developed. Crick, however, admits that this theory of Directed Panspermia, although plausible, suffers from extreme paucity of evidence. He calls it "premature". Crick the human being affirms: "Once the scale and nature of the galaxy is appreciated, it is intolerable not to know whether we are its sole inhabitants"; but Crick the scientist is cautious: "I cannot myself see just how we shall ever

Life Itself: Its Origin and Nature. By Francis Crick. Pp.192. UK ISBN 0-356-07736-5; US ISBN 0-671-25562-2. (Macdonald/Simon and Schuster: 1982.) £7.95, \$13.95.

decide how life originated".

A small measure of support for Directed Panspermia is seen in the almost uniform nature of the genetic code. Some factors, however, Crick does not consider; for example, the origin of some bacteria with properties which seem unlikely to have

evolved to meet our earthly conditions. And it is surprising that he does not mention the microfossils which suggest that eukaryotes existed at least as early as prokaryotes, although the initial gap of a billion years means that we do not know how either evolved. As for the supposedly random emergence of life in the prebiotic broth, Crick writes:

It is impossible for us to decide whether the origin of life here was a very rare event or one almost certain to have occurred;

yet elsewhere he writes of it as "an infinitely rare event" and even admits that

an honest man, armed with the knowledge available to us now, could only state that, in some sense, the origin of life appears at the moment to be almost a miracle.

I wonder, however, whether Crick's view will continue to prevail that "it seems almost impossible to give any numerical value to the probability of what seems a rather unlikely sequence of events" leading to the emergence of life. In any case the really fundamental problems remain to be solved; how DNA, RNA and enzymes were originally formed, and how the first cell, with its reproductive mechanism, came into existence.

Whether all the dense and sober argumentation of Crick can be validated, I am not in a position to judge. Such matters as available environments for life to emerge elsewhere, the length of time involved, the mode of travel and the duration of the voyage cannot be more than scientific speculation. Crick's scientific writing is lucid, magisterial and suitably cautious ("seems to be", "apparently", "so far as we know"). But in Chapter 15 ("Why Should We Care?") the tone abruptly alters. Crick the Nobel Prize winner has given way to Crick the human being. He reminds me here of those days in Cambridge when he offered a cash prize for the best secular use of a college chapel. When it comes to religious beliefs, gone are the qualifications and dogmatic certainty takes over. "Most modern scientists do not subscribe to any of them" (has he carried out a scientific survey?); and

The plain fact is that the myths of yesterday which our forebears

regarded not as myths but as the living truth, have collapsed, and while we are uncertain whether we can successfully use any of the remaining fragments, they are too rickety to stand as an organized interlocking body of beliefs [italics mine].

Francis Crick's personal convictions will doubtless be read with respect; but he would put us in his debt if he would give some explanation of their logical connection with the natural sciences of which he is such a pre-eminent practitioner. Wherein, for example, lies a scientist's "almost boundless optimism concerning his ability to forge a new set of beliefs"? It might seem to some, that the dreadful threat of thermonuclear war overhanging

the civilized world, with one-fifth of all scientists at work on defence contracts. should fill us with almost boundless pessimism. Granted, however, "the tremendous success of science, especially in the last hundred years", what is the logical connection between scientific explanation and ultimate meaning, or between scientific knowledge and ultimate belief? Or again, what is the scientific basis for the phrase "outmoded religious beliefs"? For example, is a scientific evaluation of the origin of life compatible with a theistic concept of creation? Readers may wish that Crick had here argued his case rather than merely stated his conclusion. Seen from our anthropic viewpoint, a remarkable series of "coincidences" must have taken place onwards from the initial explosion which brought the cosmos into

being, so as to make possible the eventual emergence of Homo sapiens (whether or not ours is the only form of intelligent life in the Universe). These "coincidences" certainly occurred. They may be due to complex sequences of random and meaningless events. But they are also compatible with divine providence. Crick tells us that in considering the origin of life a "gut reaction" is likely to be superficial or misleading. Not all intuitions however deserve to be described in such pejorative terms. Spiritual insights are not to be despised as adequate explanations to such questions which, despite Dr Crick's almost boundless optimism, seem to transcend the fields of scientific investigation.

Wholes and parts, meaning and mechanism

Marie Jahoda

The Reenchantment of the World. By Morris Berman. Pp.353. Hbk ISBN 0-8014-1347-0; pbk ISBN 0-8014-9225-4. (Cornell University Press:1982.) Hbk \$43.10, £24.95; pbk \$11.10, £5.95. The Turning Point: Science, Society And The Rising Culture. By Fritjof Capra. Pp.464. US ISBN 0-671-24423-X; UK ISBN 0-7045-3054-6. (Simon & Schuster/Wildwood House:1982.) \$17.50, £9.50.

The revolution in the basic assumptions of physics brought about by Einstein and by the development of quantum theory has repercussions far beyond that discipline. One of the consequences of the new physics—that the mind of the observer is a necessary ingredient of the structure of theory—has not only returned terms like "mind" or "consciousness" to respectable scientific status; more far reaching in the views of a growing number of scientists, philosophers and historians of science it also undermines the mechanistic world view that originated with Bacon, Descartes and Newton.

While physicists gradually absorbed the new ideas in their own field, others spelled out the wider implications of these revolutionary changes for the entire scientific enterprise. Michael Polanyi, for example, argued for the subjective character of all knowledge (Personal Knowledge; Routledge, 1958); Michel Foucault in the Order of Things (Tavistock, 1966) demonstrated the dominance of epistemes, the communality of tagit basic assumptions in the most diverse sciences at given historical periods - in other words, the domination of world-views in science and their periodic changes; Thomas Kuhn, in The Structure of Scientific Revolutions (University of Chicago Press, 1962 and 1977), has made the notion of shifting paradigms fashionable.

To the extent that there is agreement among these authors and with others who write in the same key, all of this amounts to a clarification, perhaps a redefinition, of the aims of science: no longer is science conceived as cumulatively proceeding to the establishment of ultimate truth about a finite number of laws that govern a finite universe; no longer can science make apodictic statements about ontological essence since the laws of nature are not simply out there but anchored in the minds of men. Rather it is a conceptual enterprise resting on unproveable basic assumptions that have changed in the past and presumably can change again.

Physicists who have made their thoughts about the philosophical implications of quantum theory explicit seem to agree with this conception of science. But the mechanistic view still dominates and the search for discovering the real essence of the world continues. Paradoxically, perhaps, the "hard" sciences are now more open to admitting subjective meaning into their theories, while the "softer" life sciences, particularly aspects of biology, progress on the mechanistic road.

The two books here under review continue the debate with several new twists. Their virtually simultaneous publication, though obviously written independently from each other, must be understood as indicating that the lines of thoughts and arguments they present are gaining ground. Otherwise their truly amazing similarity would be hard to explain. Both have the same scope, beginning with the scientific revolution, proceeding to a careful analysis of the thoughts and contributions of Descartes and Newton, and ending with a sketch of

quite similar new and gentler world-views, that do away with the body-mind dichotomy and the idea of the control of nature in favour of an ecological perspective in which the distinctions between subject and object, value and fact are deliberately blurred. Both authors are deeply impressed by what they see as a convergence with Eastern philosophy (Yin-Yang, Zen Buddhism) of the ideas in quantum physics; both condemn the excesses of reductionism in favour of holism; both write for the general reader (otherwise I would not dare to review them) but in a scholarly fashion, with detailed notes and references; both regard Gregory Bateson's Mind and Nature (Dutton, 1979) as the most seminal modern work; both have the same critically respectful attitude to Freud, while preferring the development of his ideas by Carl Jung, Wilhelm Reich, Ronald Laing and Herbert Marcuse. Finally, both are centrally concerned with describing the misery of the modern world with its violence; poverty, consumerism, alienation, inflation, drug dependence. lunatic arms race and ecological destructiveness. In this last respect they are, of course, not alone. In contrast to the Meadows' Limits of Growth (Universe Books, 1972), with which they have otherwise much in common, they are cautiously optimistic because they see the new scientific world-view already emerging in North American culture.

Differences between these two books are largely matters of emphasis. Capra, a physicist, is particularly good in describing the development of physics from Newton to the present and is careful to point out which of the modern theories he adheres to are still controversial, for example, Chew's S-matrix theory. While he represents it in a language understandable to the layman and admits that he singled it out because it supports his broader views, it remains impossible for the non-physicist to understand its significance. Berman, a historian of science, writes most interestingly about Newton's psychological conflicts and complexities, and goes altogether more into psychological and political matters. While he, as much as Capra, admires Bateson whose thoughts and sources he describes in greater detail with particular emphasis on the principle of the essential incompleteness of knowledge, he also recognizes that some of Bateson's concepts are double-edged and could be exploited for totalitarian and anti-intellectual purposes; of which he strongly disapproves.

Two major common themes in these books deserve, however, critical comment. The first is the postulated link between the current malaise in the industrialized world and the mechanistic assumptions of Newtonian science; the second and related theme is the reductionism—holism issue.

A yearning to make coherent sense out of one's experience of being alive is probably universal; in Capra and Berman, both equally alive to the crisis-ridden state of the modern world and the state of modern science, their search for coherent meaning leads them to fuse these two realms into a world-view in which they are inextricably interdependent. Theirs is one interpretation of the past course of history and its possible future trend, but in the light of their own words they are honour-bound to admit that it is a subjective interpretation and that others are possible. One cannot take exception to their yearning for a better world nor to their description of the development of science. But there are good reasons to regard the link between them as not established. Human ingenuity in creating untold misery did not wait for the development of a mechanistic world-view. When Rome burned while Nero fiddled, when underoccupied soldiers in the fourteenth century turned brigands and plundered, raped and burned the French peasantry, devastating its agriculture, very different world-views prevailed. The holistic world-views that have for thousands of years dominated thought in the Far East have not avoided hunger, violence and overpopulation, nor the Cultural Revolution. Furthermore, the assumption that for the period with which these books deal one world-view permeated societies is questionable. People did not and do not regard themselves as machines, notwithstanding the existence of robots. In their search for meaning they have turned neither to Newton nor Niels Bohr, but increasingly in the United States to curious sects, pseudoreligions, creationism, blind imitation of Eastern practices, extrasensory perception, spiritual media and astrology all of them dangerous in their thoughtlessness as Berman explicitly recognizes, but all of them nearer to the advocated world-view than to mechanistic conceptions.

If the argument is, however, that it is not the general population but those who hold political and economic power who exemplify the Newtonian system and thereby run us into destruction, one could equally well argue that their many misdeeds are the result of sharing essential ingredients of the new view: all too many political and economic pronouncements blur fact and value, object and subject, just

- Paul and Anne Ehrlich's Extinction: The Causes and Consequences of the Disappearance of Species, reviewed in last year's Autumn Books Supplement by Kenneth Mellanby (Nature 294, 41; 1981), has just been published by the UK by Gollancz. The book was originally published by Random House in the United States. Price is £9.95, \$15.95.
- A paperback edition of Biological Energy Resources, by M. Slessor and C. Lewis (reviewed in Nature 283, 316; 1980), has been published by E. & F.N. Spon, price £6.95.

as Capra and Berman advocate.

Thus one of the principal themes in these two books, the link between mechanistic science and the state of the world, stands on shaky grounds.

The other — holism versus reductionism — is treated by both authors somewhat more gingerly; both are too sophisticated to deny the enormous successes of the reductionist approach in science, but both argue that in science and the world at large holism should now replace it.

To the question of reductionism versus holism Douglas Hofstadter has surely provided the final answer in his marvellous Ant Fugue (Gödel, Escher, Bach; Harvester, 1979) with the Zen word "mu" which means: unask that question. It all depends on what one wants to know. If one is after the chemical composition of cells, holism won't do: if one wants to know how people cope with the crises of life, no reduction to physiological brain-processes will provide an answer, even though brainprocesses are required in coping with life. The step from meaning to mechanism inevitably avoids the question to which an answer was originally sought. The meaningful whole is indeed different from its constituent parts and must be studied on its level, but unless the parts are properly functioning, wholes would collapse. So the parts, whether of human being, of ant colonies, of the environment or of the planetary system must be understood too.

It is true that many scientists still regard the reductionist approach as more "scientific", whatever that may mean. But the development of systems theories is already a powerful antidote to such narrow scientism; Capra and Berman furthermore quote many good minds (and some not so good) who are already grappling from a system's point of view with the central task of all scientific enterprises: to formulate significant questions and design ways to explore their implications. Whether such questions can be raised and tackled by relying on the poetic and mystical worldview of the unity of nature where everything is interdependent with everything else seems to me doubtful. The oceanic feeling of being at one with the Universe is a wonderful experience in moments of ecstasy. For the more pedestrian rational enterprise of science it must be replaced by asking questions of partial systems, small enough not to transcend the powers of the human mind.

Capra in his preface admits that with so large a scope he may have been superficial and simplistic when discussing many diverse fields of study, but he trusts that the whole of the book will be more than the sum of its parts. In contrast, this reader found many of the parts in both books informative and interesting, but the whole a bit muddled.

Marie Jahoda is Professor Emeritus of Social Psychology and Consultant to the Science Policy Research Unit, University of Sussex.

Genesis of belief

John Maddox

Fundamentalism and American Culture: The Shaping of Twentieth Century Evangelicalism 1870–1925. By George M. Marsden. Pp. 306. ISBN 0-19-502758-2. (Oxford University Press: 1981.) £11.50, \$19.95.

LAST year's trial in Arkansas about equal time for creationism and evolution may have ended satisfactorily, but why was there in the first place a law for Judge Overton to declare unconstitutional? The wish to find out is a good reason for tackling this intricate but elegant piece of scholarship. Disappointment that there is no simple answer is overwhelmed by the richness of Dr Marsden's tale.

The book is an ecclesiastical history of the multicoloured and often warring denominations of American Protestantism in the half-century that ended in 1925 with the Scopes trial in Tennessee, Full-blown Fundamentalism was then only five years old and, Marsden says, never fully recovered from that defeat. Its end is symbolized by the death, on the Sunday after the trial ended, of William Jennings Bryan (counsel for the prosecution), once nearly President of the United States and afterwards, for a time, Woodrow Wilson's Secretary of State. But H. L. Mencken's savage obituary essay could not also serve as an epitaph for grass-roots Fundamentalism — there was too much of it. "Heave an egg out of a Pullman window and you will hit a Fundamentalist almost anywhere in the United States today."

By Marsden's account, Fundamentalism emerged from the reaction by Baptists and Presbyterians against the liberal theology taking hold in their denominations. But its origins lie in the "dispensational premillennialism" of the nineteenth century - the belief that the preordained history of the world specifies a final period (dispensation) of grace preceded by a second coming, itself the end-point of a period of social and moral degradation arranged by the Prince of Darkness. So the literal truth of the Bible, in particular the Revelation of St John the Divine, is the cornerstone of the faith, while saving souls against the second coming (Moody and Sankey in the United States, Spurgeon in Britain) is more important than social reform which might blunt the prophecy.

I had not known that the Fundamentalists own their name to the twelve-volume encyclopaedia of evangelical thought called *The Fundamentals* that was financed by the Californian oil-baron Lyman Stewart and was distributed free to more than 100,000 religious opinion-formers throughout the English-speaking world between 1910 and 1915. By then, the war between the premillennialists and the liberal theologians was well under way. There had been ructions among the Pres-

byterians about a proposed liberal revision of the "Confessions of Faith". Bible schools had sprung up, as had evangelists such as Billy Sunday — "I don't know any more about theology than a jack-rabbit knows about ping-pong, but I'm on my way to glory".

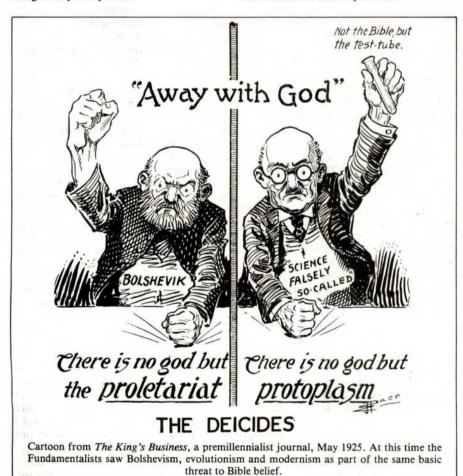

Marsden says that the Great War sharpened this conflict. Some premillennialists knew it to be the prelude to the Armageddon that had been prophesied. Bolshevism (1917) was another sign that the Prince of Darkness was at hand. The liberals, on the other hand, feared that such detachment would undermine the war effort. The social upheaval of demobilization, the financial crisis of 1919, the rise of gangsters and even the spread of cigarette smoking confirmed the premillennialists in their gloomy diagnosis. By 1920, both the Baptists and the Presbyterians were at loggerheads among themselves. The Fundamentalist crusade to purge the denominations of soft theology made the Scopes trial inevitable.

What explains the intensity of this dramatic conflict, centred, to begin with, in the north and not the south? Partly it was the nostalgic response to the final passing of the world order, signalled by the War. But Marsden persuasively explains how the tightly-knit immigrant communities of the early decades could have sensed each unfamiliar idea or unexpected event as a threat to the Protestant society they thought they had joined.

Politically, Fundamentalism was conservative (which is not the same as Republican) and fearful of an outside world seemingly rife with Bolshevism and Socialism. On balance, Marsden argues, Fundamentalism was not anti-science as such: indeed, it claimed to be the only scientific interpretation of the facts (the Bible). But evolution, "A string of guesses strung together", was a different kettle of fish. Marsden agrees that in the 1920s Fundamentalism was, for several interesting reasons, largely an American phenomenon. Perceptively, he asks what is to be made of the Fundamentalism now emerging in Islam and (in a footnote) in Ulster.

Marsden's history throws some light on those recent events in Arkansas even though 1981 is well outside his period. It explains why evolution is a unique challenge to Fundamentalism, and why Fundamentalism persists. For you cannot expect such a strong and recent tradition simply to melt away after a few set-backs in the courts. What Marsden does not for me sufficiently explain is why, in a republic in which church and state are constitutionally so separate, so many people have for so long invested so much energy and passion in such fierce and pointless arguments. "The God of your choice", it seems, demands a hard sell.

John Maddox is Editor of Nature.

Expressing science

Maeve O'Connor

Writing a Scientific Paper and Speaking at Scientific Meetings, 5th Edn. By Vernon Booth. Pp.48. (The Biochemical Society: 1981.) £2.50, \$6.

WRITING [maketh] an exact man, wrote Francis Bacon. How exact does it make scientists, already expected to be the most exact of men and women? And do they learn through writing to become not only more exact thinkers but, in turn, better writers?

Most editors would agree that although some scientists are superb writers and many are adequate, many more are imprecise, obscure, wordy or just plain careless. This is why journals tend to call for accuracy, simplicity and conciseness in their instructions to authors and why some editors devote hours to showing authors how to reach these goals. Editors and their requests for brevity are nevertheless often blamed for squeezing the life out of the socalled "literature". If blame must be assigned, however, we should direct it instead at educational systems that seem hard-pushed to produce literate graduates, never mind literate school-leavers. Yet scientists in particular, who must communicate their thinking successfully to other people if they are to help either society or their own careers, need some training in the art of presentation. Even in this age of cash crises, universities therefore ought to arrange appropriate courses. At present these are rare, but the return on the small investment needed could be enormous.

Until more courses become available, individuals could help themselves by studying one or two books on writing. Among these, Vernon Booth's booklet probably packs in the most good advice per square centimetre. This began life in 1971 as the Koch-Light Laboratories prizewinning essay. Dr Booth has revised and amplified the fourth edition (1977) and added eight pages on speaking at meetings. He does not claim to provide a complete text on how to write but simply to show readers how to avoid the mistakes he has met in scientific papers. He tells us what to do before writing, when to begin ("early") and how to get going ("Begin with the easiest section"). He gives useful hints on handling the various parts of a paper, and he covers all the commonest problems of literary style and punctuation in 12 succinct pages. In the section on speaking at scientific meetings he continues to administer sound advice, though little of this is particularly new. Like the rest, however, this section is pithily put and should be invaluable to busy scientists.

Maeve O'Connor is Senior Editor at the Ciba Foundation, London, and co-author of Writing Scientific Papers in English (Pitman, 1978).

Science in society, society in science

C.A. Russell

Between Science and Values. By Loren R. Graham. Pp.449. ISBN 0-231-05192-1. (Columbia University Press: 1981.) \$25.90, £14.40.

SCIENCE is about what is — what exists "out there" in the given world of nature. Values, however, are about what ought to be. They derive, not from ethically neutral scientific data but from the hunches of a Marx, the ambition of a Hitler, the Ten Commandments or even the Boys' Own Paper. At least, that is how the distinction is often made. On that view it is not surprising that the world between science and values has been frequently thought not to exist. Many people still believe this today, though it is a curious fact that they may arrive at such a conclusion from quite opposite directions. One group would deny the concept any validity because science and values are seen as overlapping aspects of one unified whole, each of which can expand to comprehend the other. There is no more meaningful an area "between" them than there is between the North Sea and the English Channel. Another group, however, would conceive of science and values as such different entities that they must be kept in watertight compartments and, since they must not be mixed, nothing could exist that had a little of each.

In this book such groups are labelled respectively "expansionists" and

The Strain and the Bond

She was a melancoli clone,
A prey to moods and shyness,
Who stayed at home, and grew alone —
A virtuous f-minus.

She loved another from afar: She idolized his gender. She little knew of H-fr (And less of Waring blender).

Responding to her coliform, And tempted by her colihood, The H-fr took her by storm (As willful f-rs would).

Beguiled by airy persiflage (A noxious kind of coltergeist), She caught a bout of coliphage; Succumbed to it; and lysed.

So, maidens, stay alone — and well — Remaining blithe and bonny, While other cultures go to Hell In coli matrimony.

This poem is taken from Ralph Lewin's *The Biology of Algae, And Other Verses,* recently reissued by University Press of America at \$6.75. Another taste of Professor Lewin's verse appears on p.506.

"restrictionists". The former hold that science and values did, and do, have much in common and, while in one sense there was no separate world "between" them, they were capable of the most potent interactions that could have consequences for human history of the profoundest importance. That view, rather than the opposite restrictionist one, informs this wide-ranging analysis of scientific controversy in the twentieth century. Graham begins by an examination of relativity and quantum theory, contrasting the metaphysical attitudes of Einstein and Bohr, casting a quizzical eye at the popularizing work of Eddington, and relating to their own cultures the scientific philosophies of the Soviet physicist Fock and the German Heisenberg. In the life sciences, the speculations of Bergson and Monod are followed by the rise of behavioural psychology and ethology. The author has some extremely important things to say about the cases of sociobiology and eugenics and the problems presented in biomedical ethics.

Historians of science will find much to admire in this book, not least its careful documentation, extensive bibliography and authoritative insights into problems that are rather inaccessible (as the history of Russian physics) or else are very recent. But the issues raised are not merely of academic interest; many of them are of urgent practical importance. While the author has no panacea to offer to those facing the dilemmas posed by genetic engineering, biomedical ethics and the claims of sociobiology, he suggests many useful pointers. And one clear conclusion emerges again and again: the inadequacy of restrictionism. Historical analysis repeatedly denies us the luxury of even contemplating the emergence of either science or values without the other. Expansionism is more conformable to historical reality, though prone to abuse and perversion; one need only cite the biologies of Nazi Germany and Stalinist "fraudulent Russia which were interpretations and misuses of science that could have arisen only in their particular political and social milieux" (p. 255).

By concentrating on recent science, and especially those branches concerned with man, Graham has established his case decisively. From now on behavioural psychology, genetics and other related areas of scientific enquiry will be seen by historians as inseparably involved in value-judgements almost from their conception onwards. This is a useful achievement, though not unexpected. It will be good news to those who over the past few years have assiduously sought to debunk "the myth of value-free science". They may, however, find some of Graham's other conclusions rather less welcome. Following

Toulmin and others he views science as a spectrum with the value-laden social and human sciences at one end, but with the largely value-free physical sciences at the other. His carefully documented casestudies offer some support for the view recently expressed (by D. M. MacKay) that the notion of universally value-laden science is an illogical extrapolation from the social sciences (where it is undoubtedly valid). Although his main purpose is to discover and demonstrate how science has affected values, the reverse process is considerably illumined by the author's narrative, and indeed the whole concept of value-laden science is complex enough to justify some analysis. It can mean at least five things.

First, it refers to values involved in choices made by individuals as to research career, subjects and modes of research, publication and so on, and by institutions as to whether to fund research and, if so, in what ways, and whether to exercise any control over it. In the last connection Graham concludes that a core-area of science should be exempt from such control and elsewhere much hard thinking needs to be done before exercising the control deemed necessary. No one would surely doubt that in this almost trivial sense science is always laden with values of individuals and society.

Second, science may be value-laden in terms of its theories. The author lists cases where the cognitive structure of science has been affected by systems as diverse as Puritanism, Naturphilosophie, monism, racism and Marxism, their distinctive values affecting the fabric of scientific thought. The different ways in which genetics developed in Germany and the Soviet Union during the 1930s illustrate particularly well the uptake of cultural values in the development of natural knowledge. His example of Copernicanism is perhaps less well-chosen since it may be doubted whether the decentralization of man was seen clearly by Copernicus as a demotion, whether Calvin ever did oppose the new system (p. 303), or even whether the "mountain of evidence" produced by Galileo was so regarded at the time (p. 362). But the essential point remains that Copernicus made a choice rather than a discovery, and that therefore values must have been present at the beginning. It is not going too far to suggest that most scientific theories are at least partly constrained by social values. That, however, is not to say that there is nothing to differentiate them in kind from (say) theories of politics or literature. The difference lies in the appeal to empirical data, and it is in this third area that the assaults on the concept of valuefree science are least successful. Given that "a real physical and biological world exists" (p. 25), empirical data and regularities will also exist independently of the ideology of the observer. Nowhere is this more true than in the physical sciences. Perhaps that is why Eddington could be so

sure of his restrictionist position, with his limitation of science to just "pointer readings".

The application of science to technology marks a fourth opportunity to seek for values, and they are not hard to find. Decisions as to whether and how to apply science inevitably involve valuejudgements, and few would quarrel with that assertion. A point of interest that does emerge from Graham's discussion of medical ethics is that strictly scientific knowledge plays a relatively small part in creating and solving the various dilemmas. The case of amniocentesis is instructive. Medical technology, much more than scientific research, has determined the dimensions of the problem, and the social climate is even more important.

The last kind of way in which science could be said to be value-laden is in its attempted extension and application to social problems as such. In this case it is much more true that science influences values than that it reflects them in its structure and practice. And here, in example after example, Graham demonstrates how readily this happens. He traces the story from Einstein (who, though a prolific writer on social matters, denied that science was directly related to values) to the sociobiologists' conclusion that all values are under genetic control - "the ultimate expansionism". En route he has much to tell of the ways in which science was used to justify ethical norms (as with Social Darwinism and capitalism) or even to explain them. He reminds us that several key figures, as Bohr, changed their views with time; he observes that early eugenics, far from being a tool of the Right was regarded in Weimar Germany as a Leftist deviation; and he cautions us against always supposing that "science is forcing changes in our values" (p. 267).

The author makes no attempt to conceal his own values. He emerges as a liberal and humane person, determined to see the best in ideologies with which he disagrees. Naturally some of his conclusions are highly contentious. Does it really follow, for instance, that dialectical materialism, whatever its merits, "has been damaged --probably beyond the point of salvage - by the fact that it is the political doctrine of an oppressive, nondemocratic state" (p.349)? And is restrictionism always antiscientific? What about Bacon and his two books of Nature and Scripture? And who is he that shall decide the issues of human genetics "without a priori commitments" (p. 255)? Nevertheless we can be grateful for an original, provocative and at times brilliant demonstration of the relevance of historical enquiry to critical issues of our day.

The second use of nuclear weapons

Laurence Martin

Nuclear Illusion and Reality. By Solly Zuckerman. Pp.154. UK hbk ISBN 0-00-216555-4; US 0-670-51822-0; pbk ISBN 0-00-216554-6. (Collins/Viking: 1982.) Hbk £7.50, \$10.95; pbk £4.95.

THE illusion which Lord Zuckerman mentions in his title, and which his book is chiefly devoted to exposing, is the idea that nuclear weapons could ever be used as a rational means of defence. A nuclear war would, he asserts, almost certainly become total, mutually annihilating, even if it began in a small way, which is itself improbable:

nuclear weapons may well be classified as strategic, theatre, and tactical, but these terms are meaningless if the use of one of them may mean the use of any.

In effect, then, nuclear weapons only serve to deter the use of nuclear weapons and Lord Zuckerman, while believing in the necessity for such deterrence, advocates what is usually called a "no first use" policy. Unilateral nuclear disarmament would expose the West to nuclear blackmail but, for all practical purposes, defence against aggression short of nuclear attacks must be provided by conventional forces. It is to those, argues Lord Zuckerman, in common with many voices now raised in the Trident debate, that our military energies should be vigorously directed. On the British nuclear force, he is a little ambivalent. He scoffs at the idea that British disarmament would serve as a useful example to others and, while regretting the resources diverted from conventional forces, he concedes the British force is an adequate deterrent to nuclear attacks on the United Kingdom. His most original reason for favouring the maintenance of the British and French forces is, however, that as small but effective deterrents they serve to demonstrate the superfluity of the huge forces maintained by the United States and Soviet Union.

There is clearly a good deal of plausibility in Lord Zuckerman's arguments and they are advanced with admirable lucidity. He pokes some shrewd holes in much that passes for strategic wisdom: pointing out for instance that those who cite the small CEP (Circular Error Probable) of missiles usually fail to consider the 50 per cent of warheads that will fall elsewhere, some with really gross errors; that tactical nuclear weapons have been widely distributed without any convincing doctrine for their use having been concocted even to the present day; that small nuclear warheads are not even very effective for many military purposes and that efforts to use them may consequently entail using large and devastating numbers. Nor can one fault his

lengthy explanation of what the effects of large scale nuclear war would be, though we are perhaps not lacking in earlier expositions of this theme.

For those already immersed to some degree in the nuclear debate, however. there are two threads in Lord Zuckerman's book that may be received rather cautiously. One of particular interest to readers of this journal is Lord Zuckerman's repeated attacks on the role the primary role it often appears - of science and scientists in promoting the "arms race". There is, of course, room for debate as to whether the international military competition that undeniably exists is so unlimited, and so useless, as the metaphor of race suggests. This debate is important, for the answer should influence our readiness to seize on such remedies as are proposed.

So far as the specific role of science is concerned in stimulating the competition, whatever its intensity, there are actually two kinds of scientists in Lord Zuckerman's world. The majority appear to be rather lower grade people, usually called "technicians", who work in military research establishments and foist innovations on the military and the politicians. There is also, however, a small elite of scientific advisers - in Britain including Lord Zuckerman himself, in the United States his friends Jerome Wiesner, Herbert York, Franklin Long and so on who see the uselessness of it all but whose advice never seems to have been taken when anything wrong was done. One can only admire the resolution with which they nevertheless clung on to the job.

The lesser kind of scientist is apparently the fundamental cause of our military predicament: "At base, the momentum of the arms race is undoubtedly fuelled by the technicians in governmental laboratories and in the industries which produce the armaments". There have been several recent studies of this problem, chiefly in the United States, and it undoubtedly deserves even more thought. Neither militarist nor keen disarmer should tolerate military developments that serve no useful strategic purpose. Doubtless some weapons do get made because they are "there" and sometimes, perhaps, a weapon emerges not as the result of a military specification but because a diversified technological process throws up the necessary components: possibly the cruise missile is such a case, coalescing from disparate developments in guidance, propulsion, image suppression and so on.

But this does not mean that the cruise missile is a useless or necessarily deplorable weapon or that its production is the result of spontaneous generation rather than rational strategic decision. Lord Zuckerman seems to regard the MIRV as such a

C.A. Russell is Professor of History of Science and Technology at the Open University. His most recent book, Science and Social Change, will be published by Macmillan, London, later this year.

New Bioscience Titles from Pitman

Attention and Schizophrenia

Robert D Oades

What are attention and schizophrenia? How can they be studied? This book reviews evidence as to which brain areas and systems may be involved in these phenomena. The objective is to make pharmacologists, psychiatrists, neurobiologists and behaviourists more aware of each others' problems, and to stimulate an interdisciplinary approach.

February/344 pp/Cased ISBN 0 273 08490 9/£22.00

Molecular Approaches to Evolution

Jacques Ninio

Evolutionary theory is considered in the light of modern advances in molecular biology. The fundamental aspects of molecular processes, used by the cell in order to evolve, are explained.

February/140 pp/Paper ISBN 0 273 08521 2/£5.95

Neuropharmacology of Insects

Ciba Foundation Symposium 88

This volume brings together 24 specialists in insect neurobiology, neuropharmacology, genetics and physiology. They present a thorough review of the current state of insect neuropharmacology, the position it occupies in pharmacology as a whole, and the directions it might profitably take in future.

April/340 pp/Cased ISBN 0 272 79652 2/£25.00

Competition and Coexistence of Species

A J Pontin

This much needed book reviews a developing subject for undergraduate teaching, in which no suitable monograph has previously existed and for which ecology textbooks are too brief and incomplete in coverage.

January/110 pp/Cased ISBN 0 273 08489 5/£8.95

technology- rather than strategy-led growth. Yet we know that the production of MIRVs was the subject of prolonged, agonized and explicit debate. It is surely going too far to absolve the political leadership of responsibility and assign it all back to the "technicians". It is interesting to note that in its latest Yearbook, the Stockholm International Peace Research Institute flatly repudiates the "driven by technology" thesis and affirms that the political system gets the weapons for which it calls.

Lord Zuckerman does not make very clear what he believes the main danger of the technology-driven arms race to be. Does sheer quantity of weapons make war more likely? There is no definite statement of this. It is not, apparently, that lesser quantities would do much to limit damage, for Lord Zuckerman is adamant that much smaller nuclear forces than the present ones would serve to wreak disaster. But dangerous Lord Zuckerman certainly believes the present military confrontation to be, and he despairs of survival if the East-West competition is not moderated by arms control before the end of the century. Obviously weapons secured for no logical strategic reason would be a waste of money. Reading more between than on the lines, however, it would appear that perhaps the main danger Lord Zuckerman perceives is that an unjustified reliance on nuclear elements in NATO strategy might lead to the use of nuclear weapons despite the fact that it would be irrational to do so.

Not since the first contradictions of the idea of "massive retaliation" has it been possible to deny the reality of this danger, paralleled as it is, in Kennedy's famous phrase "holocaust or humiliation", by the danger of political defeat if the threat to use nuclear weapons proves hollow. Lord Zuckerman's cry for us to look to our conventional forces, and to recognize that nuclear deterrence requires an adequate underpinning of lesser forces, is amply justified.

It is here, however, that an all-too-brief reference to a second debatable theme in the book should be made. Lord Zuckerman is an advocate of "minimal nuclear deterrence" combined with conventional defence, and almost totally rejects any idea that nuclear weapons might be used in limited ways for "warfighting" or to introduce an "intra-war" level of deterrence by nuclear means. His one concession is to admit that

it is just possible that one side might not reply in kind, say to a nuclear 'shot across the bows' or to the attempted 'discriminate' use of nuclear weapons, or even to a first strategic strike.

But he goes on to say that in practice retaliation would be unrestrained for psychological reasons and for lack of technically adequate command and control. When citing with disapproval Dr Harold Brown's statement as Secretary of Defense — as an earlier "scientific adviser" Brown gets good marks — that a

flexible strategy should "leave open the possibility of ending an exchange before the worst escalation and damage had occurred, even if avoiding escalation to mutual destruction is not likely", Lord Zuckerman says only "the final ten words of this statement are those that matter".

Whether even "not likely", if accurate - and certainly it is hard to be optimistic about such a juncture - justifies making no provision at all for "controlled" nuclear action in such a contingency is, and is likely to remain, a vexed and probably the most important strategic question of our advancing nuclear age. It is good to have Lord Zuckerman's firm view to ponder. The logic of his position leads to his "no first use" policy. But we should not accept this without first dwelling on two or three difficult questions. What is the effect of a "no first use" policy in a coalition where the main and, if many had their way, the only nuclear forces belong to a distant

Lord Zuckerman - a view to ponder

ally? If nuclear attack on Western Europe may not be regarded as a "first use" on the United States, should the United States have an identifiable separate level of "retaliation" to deter in such cases? And if a future war in Europe is given a virtually assured "conventional" character, by a "no first use" policy, would the calculation facing a would-be Soviet aggressor—"Can I win a conventional war in Europe"— be dangerously different from the one facing him today—"Can I afford to start a war in which nuclear weapons will probably be used"?

In practice, the balance of deterrence in Europe is probably stable over a wide range of strategic postures, because the stakes are so high and the all-pervasive aura of nuclear fear is so daunting, whatever the explicit strategic doctrines. But in the long run, underlying assumptions about how nuclear deterrence is related to overall deterrence must have profound effects on how states prepare in peacetime and might behave in war. For those who think such questions important, Lord Zuckerman's book offers a provocative and forthright essay well worth the reading.

Laurence Martin, Vice-Chancellor of the University of Newcastle upon Tyne, was Professor of War Studies at the University of London from 1968 to 1977. He delivered the 1981 BBC Reith Lecture, "Armed Force in the Modern World".

Quantum theory: certainty in uncertainty

P. W. Atkins

The Cosmic Code: Quantum Physics as the Language of Nature. By Heinz R. Pagels. Pp.370. ISBN 0-671-24802-2. (Simon & Schuster: 1982.) \$17.50.

THIS is a book aimed squarely at the general reader with the intention of conveying not only the excitement of modern science but also the revolution in our comprehension of the world that accompanied the introduction of quantum theory. There are three parts: an account of quantum theory; a description of modern particle physics; and a brief personal reflection on the nature of physical laws. The material is presented nonmathematically and will be accessible to anyone who is interested in what the author rightly regards as the nonpareil of this century's social and cultural events. The text itself is characterized by the author's almost boyish eagerness to communicate his enthusiasm, and is sometimes so anxious to please that it trips over its own naivety ("Most physicists enjoy the outdoors") to the point, in one place, of ascribing the well-known allegory of Paley's watch to a speaker at a recent conference.

The most important section is the first, which occupies about half the book. It is woven around the biography of Einstein and his transition from being a revolutionary innovator to one who lost "his hot-line to the Old One" and refused to accept that determinism was dead. The intention of the section, apart from emphasizing a moral, is to present an exposition of quantum weirdness; the loss of objectivity, its replacement by an observer-created reality and the rejection of determinism - "the quantum theory is a theory of an instrumentally detected material reality" (p.99). Underlying (if not stemming from) this intention is an opposition to material reductionism (a programme that "cannot be carried out", p.135). The basis of this view is an acceptance of the Copenhagen interpretation of quantum mechanics with its emphasis on the meaninglessness of a concept until its mode of measurement has been defined. Pagels adopts the party line on this issue, and as such does a very good job. His argument leads, convincingly, to the ultimate quantum weirdness that "human intention influences the structure of the world" (p. 95), and the view that "quantum reality" is statistical.

Convincingly, that is, until one stops to think. In my view, for what it is worth, determinism entered physics with the uncertainty principle, and the principal confusion pervading so much interpretative commentary on quantum mechanics (and finding such lucid expression in this book) is the failure to distinguish between measurement and

specification. I should explain what I mean. With quantum theory we first encountered a constraint on our description of the world. Classical mechanics attempted unknowingly to be overcomplete in its specification; quantum mechanics is the first theory we have (and possibly the last we shall need) that respects nature by refraining from imposing a description too strong for it to support. Quantum mechanics is fully deterministic in the sense that the evolution of a state under the influence of a hamiltonian is perfectly well-defined; it ceases being deterministic only when we insist upon reverting to an overcomplete discussion by asking questions that classical mechanics has conditioned us to believe are answerable or when, after we have prepared a system in an eigenstate of one observable, we seek to predict the outcome of another observation that classical mechanics has conditioned us to expect but which quantum mechanics proscribes. No wonder our predictions then squirt out in all directions! Quantum "randomness" is nothing more than this reaction to false expectation. Likewise, the strict Copenhagen requirement of "meaningless until measured" is a confusion between a mode of interpretation and a manner of exhibiting self-consistency (or at least of constructing thought experiments to show that there is no inconsistency). This viewpoint is consistent with Einstein's whose views, I suspect, have been overborne by the appeal of an interpretation that hangs on to classical modes of thought. This emphasizes yet again the delicacy of the balance in the dictum (p.67) that "physicists are conservative revolutionaries pseudoscientists lack that commitment to existing principles".

My position then is strict determinism (or better, neodeterminism, because it must not be confused with classical determinism) showing itself as indeterminism only when false, culturally conditioned, classical questions are asked. Hence, in my view, Pagels has focused on a wholly misleading and fallacious interpretation which cannot fail to imbue his readers with a false impression of the nature of "quantum reality". I have to admit, though, that he has the forces of neoconvention ranged on his side (which does not mean he is right), and readers of this engaging book will leave it with a clear grasp of a conventional and widely accepted interpretation.

I have concentrated on a single aspect of the book, but one that lies at its core. There are many other remarks with which the careful reader will probably disagree. For instance, I could criticize at equal length the remarks to the effect that differences between macroscopic and microscopic phenomena are qualitative and not merely quantitative (p.128), that historical events are not reducible to individual acts on the part of human beings (p.131), and that quantum reality is statistical and therefore outside mathematics (p.337). There is also a peculiar blindness to the technical meaning of a "selfish" gene but not to its analogue "charm". There is also much to admire, especially the author's manifest deep concern to communicate.

P. W. Atkins is a Fellow of Lincoln College, Oxford, and author of The Creation (W. H. Freeman, 1981).

Getting JET off the ground

John B. Adams

A European Experiment: The Launching of the JET Project. By Denis Willson. Pp.181. Hbk ISBN 0-85274-543-5; pbk ISBN 0-85274-549-4. (Adam Hilger/Heyden: 1981.) Hbk £10.50, \$23; pbk £6.95, \$15.50.

EVERYBODY who is concerned in Western European affairs should be interested in this account of "a European experiment". Opponents of the European Community system will find in it ample confirmation of their criticisms; supporters will see in it a triumph of the European spirit over national self-interest. For those who are convinced that international action is now the only way of carrying out major scientific enterprises in Europe, it will come as a sobering reminder of how very difficult it is to reach agreement at the European level.

The subject of the book is the launching of the Joint European Torus (JET) project, the latest and largest experiment in the world-wide effort which started back in the 1950s to exploit nuclear fusion reactions as a useful energy source. To make this dramatic story (or lamentable comedy as it was once described) intelligible to the layperson, the author has first to explain something about plasma physics, the general history of nuclear fusion research and the complexities of the European Community system, all of which he does with commendable clarity. Having provided the reader with the essential background information, he then describes the specific problems presented by JET.

The principal difficulty that arose in the launching process and the reason for the two-year delay in the approval of the project was the problem of where to locate it. After the failure of the Community to agree to a common nuclear fission reactor programme and the consequent disarray this caused to the Euratom laboratory at ISPRA; which was set up to carry out that programme, the Commission devised a

JET takes form — the eight limbs are part of the transformer core of the machine, currently under construction in the Torus Hall at Culham.

different method for pursuing nuclear fusion research in Europe. This was to set up a coordinated research programme using the existing national fusion laboratories rather than to try to bring all the work together in a single European laboratory. This method proved acceptable to the national laboratories and to the Governments concerned, and it worked very well until the JET experiment came along. Because of its large size and the need to engage most of the national laboratories in its design and construction, it did not easily fit into the established pattern. A new system was adopted, called a Joint Undertaking, which made JET a common European enterprise. But there was no European fusion laboratory in which to build it.

The Commission first suggested that JET should be built at ISPRA where there were resources then under-utilized. This proposal was opposed by many of the fusion scientists who feared that the project would be seriously handicapped by the absence of fusion expertise at ISPRA and by its previous history. It was also opposed by several member states, who saw JET as a desirable acquisition and who proposed alternative sites for it on their own territories. The scene was thus set for a first-class battle for the JET site in which all of the many levels of the Community became involved, and it is this battle which forms the main drama of the book.

Denis Willson describes these events, blow by blow, with great objectivity and with refreshing frankness which makes his book a very valuable account of the trials and tribulations of those who have the need and the courage - to launch international projects in Europe. It may even be used to avoid similar problems arising again in the future but, as the author points out, the Governments in Europe still have no agreed way of resolving such problems and it is difficult to see how they will acquire one as long as they insist on unanimity (which, incidentally, they had finally to forego to reach a decision on JET). But, despite all the difficulties, JET was finally approved and is now under construction next to the British nuclear fusion laboratory at Culham where it appears to be going very well.

Similar dilemmas faced by CERN, the European Organization for Nuclear Research, are occasionally quoted for comparison but it is not mentioned that it took CERN much more than two years to reach a decision on where to build its SPS machine. This problem was finally resolved

when the scientists involved agreed to reshape that project and themselves proposed the only site where it could be built—something which the scientists in the national fusion laboratories were apparently unable to do for JET.

This book is a well-written and thoughtprovoking account of a European experiment in all senses by someone who played a key role in the launching of JET and who had access to all of the documentation. It can and should be read and digested by all serious-minded citizens of Europe — politicians, civil servants, scientists and laypersons — and it will surely be read and noted by similar people in other regions of the world.

Sir John Adams, currently at CERN, was Director of the Culham Laboratory from 1960 to 1967.

Space for science?

John Noble Wilford

Beyond the Atmosphere: Early Years of Space Science. By Homer E. Newell. Pp.497. ISBN 0-80-607146. (NASA Scientific and Technical Information Branch: 1981.) Hbk \$12.50; pbk \$9.50.

FROM the start, in 1958, the National Aeronautics and Space Administration and the scientific community have had an uneasy and ambivalent relationship. It was probably unavoidable. For all their shared interests in exploration, they approached the space age with different priorities and expectations. Scientists saw in NASA a new source of research funding and of opportunities to study Earth, the Solar System and the Universe. While NASA was not ungenerous in its early dealings with scientists, its administrators marched to a different drummer. Given their political mandate, which was to establish the United States as the pre-eminent space power, the NASA managers accorded highest priority to projects aimed at "catching up" with and eventually "beating" the Soviet Union. Scientists had no choice but to accept a secondary role in the Apollo Project, for example, and to live with a relatively small share of the space budgets, now as then. Tensions between them and NASA have been an inevitable consequence.

The potential for conflict has, if anything, risen since the Apollo days. Even at the height of the Apollo mobilization, not a year went by without the initiation of a new space-science project. A small share of ample budgets paid for a lot of science. Post-Apollo budget reductions, however, coupled with inflation and the expense of the space shuttle, have now squeezed space science to the point of near-paralysis. New projects are rare, and existing ones are forever being threatened with deferral or cancellation, a fate that recently befell the Venus Orbiting Imaging Radar Mission and the American half of the International Solar Polar Mission. Only desperate lobbying by scientists, led by Carl Sagan, saved the Galileo Project from extinction this year.

In this context of uncertainty verging on despair, scientists will read Homer E. Newell's Beyond the Atmosphere with a sense of nostalgia for the early days of space science. Dr Newell, who retired in 1973 as NASA's associate administrator, bore much of the responsibility for mediating NASA's relationship with scientists so that a vigorous space-science programme was possible. He is a scientist himself who brought to his job considerable experience in managing Government science undertakings. His book is another in a series of histories prepared under NASA auspices, which means that it is, in a sense, "official history", though somewhat more candid than most works of this

Much of the book reviews the origins of space science as a part of NASA's operations and the achievements of NASAfinanced research from 1958 to the mid-1970s. Space science, the way Dr Newell uses the term, is the multidisciplinary pursuit of a knowledge made possible or significantly aided by rockets and spacecraft. The breadth of the field as it evolved is impressive: geodesy, meteorology, atmospheric and ionospheric physics, magnetospheric research ("a genuine product of the space age"), lunar and planetary science, solar studies, galactic astronomy, relativity and cosmology as well as the life sciences and exo-

Dr Newell acknowledges that the expanding perspective afforded by spaceflight has yet to produce any scientific revolution. But he writes with understandable pride of the "continuing harvest" of knowledge from space science, notably in the earth and planetary fields:

No longer was the geophysicist confined to a study of only one body of the solar system. No longer was the study of the planets solely a venture of the astronomers. The dearth of new data that had led planetary studies into the doldrums and even disrepute... gave way to a sudden flood of new information that reawakened the astonomer's interest.

Other exciting developments included the effect on astronomy of space observations in the hitherto hidden wavelengths and the

discovery of Earth's magnetosphere, not suspected beforehand.

For those scientists who have worked in NASA projects, or expect to, Dr Newell's concluding chapters will be of greatest interest. They deal with "the real world of budgets and finances". They seem at times to be a plea for more understanding by scientists of how competitive are the claims for NASA's favour.

Dr Newell is perhaps still too much the diplomat to render a critical historical treatment of the struggle between scientists and engineers within NASA and between unmanned and manned programmes. Such struggles persist to this day. The author, taking note of bitter feelings among scientists towards the manned programme, does remind them that even if they had succeeded in reducing or cancelling a project such as Apollo, there was little likelihood that much, if any, of the money saved would have been diverted to them. To the contrary, he observes, science generally benefited from Apollo by riding on its coattails for such lunar science endeavours as Surveyor and Lunar Orbiter. Moreover, he contends that scientists should have been grateful that they had a civilian agency like NASA rather than having to depend on military suppport, as had been the case in the pre-Sputnik days.

As for the future, Dr Newell proffers cautious optimism about the place of space science in NASA's operations, or at least he puts the best light on post-Apollo developments. Out of the "searching scrutiny" in the early 1970s, he writes, "emerged an acceptance of a continuing role for the agency in which science, applications, and exploration would all play a part". Moreover, the author says, NASA's position became "intrinsically stronger" because it is now "freed at last from an uneasy dependence on a passing sense of urgency over the nation's technological strength relative that of the USSR".

A failure of the book is the absence of any critical evaluation of the structure for the support of space science as it has evolved. Would space science be served better if it could count on several major sources of funds, not just NASA?

Dr Newell does advise that scientists must scale down some of their expectations if they are to win continuing support from NASA. These words are only now being heeded. Resistance by recent Administrations to large, new projects — the expensive planetary missions in particular — has prompted scientists working with NASA to shift their thinking to more modest goals.

Accordingly, the Space Science Exploration Committee, formed by NASA last year and chaired by Noel Hinners, Director of the National Air and Space Museum, is devising a new strategy. Missions with limited, specialized scientific objectives, employing lower-cost, standardized spacecraft, would be emphasized. Major undertakings, on the scale of another Viking or Space Telescope, would have little or no

place in planning for the foreseeable future.

It remains to be seen how acceptable this modest strategy will be to NASA's managers or the Reagan Administration. A review of the American space programme, being prepared now by the White House Office of Science and Technology Policy, will presumably have more influence on the future course of NASA than any group of scientists. If the Administration's pronouncements are any indication, the review will deal almost exclusively with the space shuttle and policy regarding NASA's jurisdiction vis-à-vis the Department of Defense. Meanwhile, the engineers in NASA are drawing up plans for another big project, the manned space station, that would probably absorb any funds released as a result of the shuttle's completion.

This can only give scientists new reason to be uneasy. The entire American space programme is in a state of flux, with the ascendancy of the Pentagon in space affairs and the re-ordering of NASA's goals and responsibilities. It is in times like these that space scientists may find themselves wishing Homer Newell was still in a position to attend to their interests within the chambers of NASA.

John Noble Wilford is a science correspondent of The New York Times who covers NASA. His most recent book is The Mapmakers (Junction Books/Knopf, 1982).

Heroes of AI

Richard Gregory

Science Observed: Essays Out of My Mind. By Jeremy Bernstein. Pp.376. ISBN 0-465-07340-9. (Basic Books: 1982.) \$16.95.

This is a personal account, in 17 essays, of recent highlights of physics and of artificial intelligence. The pieces are written in lively style by Jeremy Bernstein, a professor of physics and author of several well-known books, including A Comprehensible World, (1961), The Analytical Engine (1964), Einstein (1973), Experiencing Science (1978) and Hans Bethe: Prophet of Energy (1980). He also writes on science for the New Yorker.

Like ancient sagas, these essays are based on heroes, on men of science confronting the unknown and sometimes each other. Chief among them are Marvin Minsky, Einstein, Robert Oppenheimer, Schrödinger and Harold Furth. Others lie in the shadows, seen with fleeting ambiguities: Ernst Mach — father and disowner of relativism. Charles Babbage—grandfather of artificial intelligence, who set out to weave algebraic patterns with his

analytical engine, just as the Jacquard loom weaves flowers and leaves. Babbage spoke most clearly through the voice of Ada Augusta, Countess of Lovelace, rejected daughter of the poet Byron. And Alan Turing — father of artificial intelligence, who dared to oppose the wit of men against machines, to see if under their disguises men and machine are the same. (Or is oil thicker than blood?)

The first principal hero is the guiding genius of artificial intelligence at MIT, Marvin Minsky. Indeed he is, as I know by acquaintance and not only description, all that Jeremy Bernstein claims. With his equally brilliant colleague John MacCarthy, now at Stanford, he started the AI enterprise in the United States in the late 1950s, and they invented its name. "Artificial intelligence" is philosophically better than the rival "Machine intelligence", for if brains are intelligent machines the colours may get confused.

Minsky is a compelling writer as well as a delightful companion and true inspirer of students. Disarmingly, he dislikes the activity of programming, preferring to think and discuss and write in words. Of intelligence, Minsky wrote in 1961 (quoted on p.54): "To me 'intelligence' seems to denote little more than the complex of performances which we happen to respect, but not understand". And, "Programmers, too, know that there is never any 'heart' in a program. There are high level routines in each program, but all they do is dictate that if such and such, then transfer to such and such a subroutine". And, "When we look at the low-level routines, which actually 'do the work', we find senseless loops and sequences of trivial operations, merely carrying out the dictates of their superiors".

There is much of interest here on the history of computing, with figures of the sizes and costs and weights and energy consumptions, as well as the speed and power of ancient and modern computers through their generations. It is indeed astonishing that ENIAC, which in the late 1940s was the most complicated electronic device ever built, was a hundred feet long, ten feet high and three deep. It consumed 140 kilowatts, to handle twenty ten-digit "words" in its memory. On this scale, one could not get a present-day home computer into the house, or even the street.

Jeremy Bernstein is a scientist writing for scientists. He assumes that one knows about Mach's principle and Newton's bucket; and he also comments economically and without gush on such matters as the idiocy of using troops to test the effects of atom bomb blast and how well they would stand up psychologically to nuclear war. These are extremely readable sagas of our age; and they are well worth reading.

Richard Gregory is Professor of Neuropsychology and Director of the Brain and Perception Laboratory at the University of Bristol.

What skulduggery?

Steve Blinkhorn

The Mismeasure of Man. By Stephen J. Gould. Pp.352. ISBN 0-393-01489-4. (W.W. Norton: 1981.) \$14.95, £9.95.

WITH a glittering prose style and as honestly held a set of prejudices as you could hope to meet in a day's crusading, S.J. Gould presents his attempt at identifying the fatal flaw in the theory and measurement of intelligence. Of course everyone knows there must be a fatal flaw, but so far reports of its discovery have been consistently premature.

The theme of this particular book is that since science is embedded in society, one must expect to find the prejudices of the age presented by scientists as fact. Most authors, given such a theme, would be content to document and catalogue instances in support of the proposition. Gould, however, goes one better by writing a book which exemplifies its own thesis.

It is a masterpiece of propaganda, researched in the service of a point of view rather than written from a fund of knowledge. For the best propaganda requires not the suppression or distortion of facts but their careful selection, emphasis and juxtaposition. So, in a work which declares its concern to be with the notion of intelligence as a single measurable "thing" in the head, we find that two-thirds of the argument is given over to a careful reworking of early attempts to establish craniometric and anthropometric criteria of intelligence, and an admirably disturbing account of the Gadarene rush to press IQ tests into the service of social engineering in the USA in the first half of this century. As Gould rightly emphasizes, many of the uses to which tests were put made mockery of their original purpose.

Ottery

A fitter fits;
A cutter cuts;
And an aircraft spotter spots;
A baby-sitter
Baby-sits —
But an otter never ots.

Though sinners sin
And thinners thin
And paper-blotters blot;
I've' never yet
Had letters let
Or seen an otter ot.

A batter bats (Or scatters scats); A potting shed's for potting: But no one's found

A bounder bound

Or caught an otter otting.

From The Biology of Algae by Ralph Lewin. See p.500 for details,

The final third of the book is the attempt proper to debunk the notion of general intelligence as arising specifically in the school of factor analysts starting with Spearman. But by this stage the reader has been presented with sufficient examples, sufficiently carefully examined, of racial and social prejudice in the work of scientists, of distorted data, fudged analysis and twisted interpretation as to the inexpert might establish a necessary connection. Add to that the soft target of Cyril Burt. some rather inaccurate observations on the role and effects of the 11+ examination system in Britain and a remarkably detailed account of antique methods of factor analysis, and you have all the makings of a lively, plausible, opinionated and zesty potboiler.

But verbal fluency is no substitute for good arguments in the long run. The substantive discussion of the theory of intelligence stops at the stage it was in more than a quarter of a century ago. Consequently there is no account of attempts to characterize the psychological nature of general intelligence, no indication that multivariate methods have progressed beyond Thurstonian techniques, no discussion of the effects of ageing, of brain damage, of compensatory programmes, no account of modern behavioural genetics, of heritability studies other than Burt's, no hint of the current interest in cybernetic models or recent attempts by experimental cognitive psychologists to account for psychometric findings.

Gould even gives a perfectly straightforward account of what heritability would and would not mean in terms of the modifiability of intelligence, but fails to point out that such arch-hereditarians as Eysenck and Jensen have published essentially identical accounts. One is, presumably, meant to conclude that adherence to the notion that there is a measurable single dimension of intelligence necessarily involves the kind of radical nativism which was prevalent in times when genetic theory and statistical methods were in their infancy.

But this is a book with a double punchline. Or to put it another way. Gould performs the remarkable trick of pulling the rug from under his own feet whilst appearing to stand stock still. For not only does he propose a totally unobjectionable definition of intelligence ("the ability to face problems in an unprogrammed . . . manner"), which, far from being novel, is a nice rewording of a definition proposed by Cattell in the context of a heavily factoranalytic theory and something of a commonplace amongst the intellectual heirs of Spearman, he even proposes essentially craniometric criteria of neoteny as a basis for the adaptability of Homo sapiens, and produces a photographic comparison of adult and infant chimpanzees with the remark that "if a picture's worth a thousand words . . . ".

The truth of the matter is that Gould has

nothing to say which is both accurate and at issue when it comes to substantive or methodological points. His "fatal flaw" (the purported dependence of the notion of general intelligence on details of factor analytic technique), the unsupported assertion that "disadvantaged" groups always perform worse on IO tests, his strictures on the application of the notion of intelligence across species boundaries, his attempt to link the use of IQ tests in Britain with a rigid class structure, all have the routine flavour of Radio Moscow news broadcasts when there really is no crisis to shout about. You have to admire the skill in presentation, but what a waste of talent.

Steve Blinkhorn, a Senior Lecturer in Psychology at Hatfield Polytechnic, is currently working at the Neuropsychology Laboratory, Stanford University.

Beyond selfish genes

Sydney Brenner

The Extended Phenotype: The Gene as the Unit of Selection. By Richard Dawkins. Pp.307. ISBN 0-7167-1358-6. (W.H. Freeman: 1981.) £9.95, \$19.95.

This book, as Richard Dawkins states in his first chapter, "is a work of unabashed advocacy". It does not put forward new theories or new facts, but it advocates a special way of looking at living things and the worlds they inhabit.

This point of view, called the extended phenotype, is a development of the ideas discussed in his earlier book The Selfish Gene where, it may be remembered. Dawkins aimed to dispose of the organism as the unit of natural selection. He argues that this unit is the gene, or, rather, entities which are called germ line replicators, of which genes are the most important examples. Adaptations are for the benefit of these elements and not for anything else. Of course, it is admitted that these replicators are useless by themselves (you can buy them in bottles as chemicals called DNA) because selection judges them only by their effects in other entities, called vehicles, which the replicators inhabit. Biologists have given one such discrete vehicle, the organism, a special role as a unit of structure and function and it is this hold that Dawkins wants to break. He claims that replicators have extended phenotypic effects, reaching out beyond the boundaries of the organisms where they happen to be lodged into the world outside, even entering other organisms. He wants to dissolve organisms:

We see through them to the replicating fragments of DNA within, and we see the wider world as an arena in which these genetic fragments play out their tournaments of manipulative skill. Genes manipulate the world

and shape it to assist their replication.

Later he speaks of the

image of a turmoil of selfish replicators, battling for their own survival at the expense of their alleles, reaching unimpeded through individual body walls as though these walls were transparent, interacting with the world....

The extended phenotype is certainly a big idea and it is pressed hard in dramatic language. But does it help to view genes as active agents, manipulating, reaching, battling? I think it only obscures the essential feature of living organisms which distinguishes them from all other complex natural systems and which gives them the capacity for evolution. It is that they are propagated by passing on not themselves but an internal representation of themselves in their genes. Exactly how this correspondence is implemented is what most biologists study; knowing it must be important if only for understanding what genetic variation can generate. To a molecular biologist, all the stuff around the genes is anything but transparent; it is hard • to see the replicators through the fog of complicated machinery, nor do they reach out so easily as Dawkins wants them to.

Dawkins still has to come grips with this central issue. In a section on the poverty of preformationism he would like to make a distinction between the central dogma of molecular genetics and that of embryology. The former states that information in protein cannot be translated back to nucleic acids: the equivalent in development is that "bodily form and behaviour may not be translated back into proteins". I think we agree that the former is a fact, not a question of principle, but why does Dawkins want to make the latter a principle and not simply an equivalent fact? After all, in the end we shall need to explain the effects of genes on bodily form and behaviour in terms of proteins; that is the only way for us to reach into organisms and for genes to reach out into the world. The molecular, cellular and organismic grammar connecting genes and phenotypic effects is the heart of the matter and the only way to explain how random changes in DNA can produce all the sense we observe in the living world.

Organisms exist. Even Dawkins realizes that he needs to bring back individual organisms. His extreme position has forced him into calling the organism a "phenomenon that needs explanation", and he offers only a summary sketch on the last page. He says:

It has paid replicators to behave gregariously. The phenotypic power by which they ensure their survival is in principle extended and unbounded. In practice the organism has arisen as a bounded local concentration, a shared knot of replicator power.

Sounds terrific, but what does it mean?

The whys (and wherefores) of behaviour

Aubrey Manning

Ethology: Its Nature and Relations with Other Sciences. By Robert A. Hinde. Pp.320. Hbk ISBN 0-19-520370-4; pbk ISBN 0-00-636237-0. (Oxford University Press/Fontana: 1982.) Hbk £9.20, \$15.95; pbk £2.95.

ETHOLOGISTS are no longer a distinctive breed; indeed the days when one could recognize them from their background and framework of theory were quite short. Large parts of the original theory built up from Lorenz's dichotomizing between the "innate" and the "acquired" in behaviour, and the energy model of drives, have been abandoned. What has endured is an approach to the animal in its natural environment which is highly productive and infectious. When Lorenz and Tinbergen built up their schools following the Second World War, ethology came as an invigorating breeze across the arid fields of so much of the white rat experimental psychology of the day. Its influence has persisted and spread widely into other areas of behavioural science.

Robert Hinde's book sets out to give an account of modern ethology and to examine this influence. He succeeds well and this is both a useful and a stimulating book. I particularly liked the brief historical introduction to each section. Since modern ethology only goes back about 30 years and Hinde himself has been a highly influential figure over most of this period, we get a direct picture of an emerging discipline as it interacts with others already established.

The plan of Hinde's opening section on "core ethology" derives from Tinbergen's classic paper of 1963, "On the Aims and Methods of Ethology". This was a landmark in the history of the subject and it represented a clear break of approach between Lorenz, who then had just published a reaffirmation of his own unchanging views on innate behaviour, and Tinbergen, who saw far more clearly that the old dichotomies (nature or nurture etc.) would no longer do. Tinbergen enunciated four types of question in relation to behaviour: those concerning its immediate causation, its development, its function (in the sense of survival value) and its evolution. Hinde has chapters covering each of these topics - he calls them ethology's four "whys". In fact they form a very good introduction which both covers some of the classic ethological studies and is also right up to date.

There is no introduction to this new Masterguides series itself and I am uncertain what audience they seek. Other titles include Religion, Law and Social Anthropology, so I imagine that "the educated layman" is once more in mind. Hinde is certainly not writing at an elementary level, nor can he bear to let

first-stage simplifications stand. Readers without some behavioural background will find parts rather heavy going and there are one or two over-complex diagrams. References to the literature abound on almost every page, and no doubt or inadequacy of the evidence is left unexposed. Just these latter qualities, of course, will commend the book to the serious student. Its main body is Hinde's assessment of the influence which ethology has had upon related fields in biology and the human social sciences. They cover a huge range, from ecology to psychiatry, and are consistently illuminating. Hinde's coverage of the literature is extraordinary and he provides good linking passages so that an overall picture of the interrelationships of these fields is built up.

Within the biological sciences Hinde includes comparative and experimental psychology whose interactions with ethology were often stormy. The personalities, as well as the scientific achievements, of people such as Schneirla. Lehrman and Beach were of great importance in determining the course of the interchanges and Hinde gives enough of the history to make us fully aware that science is a human activity. The influence of ethology in the human social sciences has also met with opposition. The contributions it can provide are, first, the comparative method, revealing the human species as one amongst many which may share certain attributes, and secondly a secure descriptive method for the early stages of behavioural analysis. Neither of these appealed to those social scientists who emphasized the uniqueness of the human species or who concentrated solely on the cognitive and perceptual aspects of human behaviour.

Such extreme positions are rarer now. The study of non-verbal communication. of the attachment between mothers and infants and of the effects of maternal separation have all very obviously gained from ethological techniques and concepts. Hinde himself has made valuable contributions in these areas and his sharp and revealing focus is clearest in these sections of the book. The critical edge is somewhat blunted when dealing with the biological approach to anthropology where some of the wilder shores of sociobiology are dwelt upon rather too gently, but all is brought back into balance in his concluding remarks.

This book will be of great value to students and teachers in other fields who want to broaden their ethological horizons. It also provides a liberal education in these other fields for more biologically based ethologists.

Aubrey Manning is Professor of Natural History in the University of Edinburgh.

An ode to adaptive transformation

Niles Eldredge

Darwinism Defended: A Guide to the Evolution Controversies. By Michael Ruse. Pp.376. ISBN 0-201-06273-9. (Addison Wesley:1982.) \$12.50, £8.40.

THINGS seem a bit frenetic in evolutionary biology these days. The casual observer might well think that the only theme imposing unity on this sphere of science is creationism: all evolutionary biologists agree that life has evolved, and all become willing allies in the political fight sparked by the recent successes of "scientific creationism" - which, however paltry its specific claims about natural history may be, asserts positively that life has not evolved. But beyond this simple and totally understandable closing of ranks, most observers see the current situation in evolutionary theory - where the object is to explain how, not if, life evolves - as bordering on total chaos. Seemingly, no two evolutionary biologists think alike these days, and we are less agreed upon things than we collectively were, say, a decade ago.

There is some substance to this view of disarray, but it has been exaggerated; we are more like a house divided than a potpourri of randomly diversified opinion. The basic problem is this:

FUSARIUM:

Diseases, Biology, & Taxonomy

ed by P E Nelson, T A Toussoun, & R J Cook

This volume brings together what is currently known about the pathology, ecology, genetics, cytology, physiology, biology, and taxonomy of this important fungus genus.

Penn State University Press, April, 560 pp, 7" x 10", 65 illus, £27 65

NATURAL HERITAGE

Classification, Inventory & Information

by Albert E Radford, Deborah K Otte, Lee J Otte, Jimmy R Massey, Paul Whitson, & contributors

The ultimate goals of this study are to foster the conservation of natural heritage, to advance field training in ecology, systematics, and evolution, and to determine site-population relationships for species of special concern.

University of North Carolina Press, 485 pp, 8½ x 11", maps & figures, £17 50

> AUPG 1 Gower Street London WC1

molecular and developmental biologists, systematists and palaeontologists all think their data have something to do with evolution. This is reasonable on the face of it because, whatever else it might be, evolution involves the modification of DNA sequences, development patterns, and species and higher taxa. And the latest news from Precambrian palaeontology tells us that the process has been going on for a minimum of three-and-a-half billion years.

On the other hand we have an evolutionary theory - the "modern synthesis" - that insists that all such evolutionary phenomena are entailed by the neo-Darwinian paradigm: organisms within populations vary amongst themselves, offspring tend to resemble their parents, and because in each generation more are usually produced than can possibly survive and contribute genes to the next generation, we get deterministic, albeit statistical, patterns of change in genetic representation in succeeding generations. This, of course, is natural selection. We now feel we know more than Darwin did about why organisms resemble their parents, and what the proximate and ultimate sources of variation might be. This understanding, plus Darwin's basic arguments, combine to yield the neo-Darwinian paradigm. No less an authority than Ernst Mayr (for example in his prologue to The Evolutionary Synthesis: Harvard University Press. 1980), has written that the "modern synthesis" is simply this paradigm of adaptive transformation plus a single additional concept: all evolutionary phenomena, of whatever scale - from molecules to phyla — are explicable in the familiar terms of population genetics. In the apt (if by now rather trite) phrase, the theory is both necessary and sufficient to explain all known aspects of evolutionary history. However oversimplified such a characterization of the synthesis may be, it fits to a T the viewpoint espoused by Michael Ruse in his new book, Darwinism Defended: A Guide to the Evolution Controversies.

The simple statements of the synthesis have long been taken as very general: all sorts of phenomena which hitherto seemed to cry out for separate explanations could all now be explained under one general theory of adaptive change. And, after all, if life has had a single history, it is indeed logical to assume that there must be a single, integrated theory of the process that engendered that single history. But now the synthesis is beginning to look exceedingly narrow. For consider the effect the synthesis has had: contrary to Ruse's enthusiasm for natural selection as a "research tool", the real effect has been the relegation of molecular and

developmental biology, systematics and palaeontology to the role of mere reportage. Evolutionarily-inclined members of these diverse disciplines have been told, in effect, to sit back, relax and simply recount the results of the evolutionary process — and leave it to the population geneticists to explain how it all happened. From time to time, members of one or more of these various satellite evolutionary disciplines have objected, insisting once again that their data - their molecules and fossils - must have something more direct to say about the validity of this or that notion about how life really does evolve. Now their voices are becoming more strident.

Michael Ruse is aware of this state of affairs. Hence the book, which has two titles, accurately conveys his priorities. First, it is a stout defence of what Ruse calls Darwinism. Secondly, and only through the glasses of a truly arch-conservative, the book touches upon virtually all the major issues of which I am aware. I call Ruse an arch-conservative advisedly: to this staunch defensor fidei, genetic drift is still a heresy. Anything smacking of the stochastic, or even of "neutrality", has him shaking his head and wagging his finger in a trice.

Darwinism, to Ruse, seems to be adaptation through natural selection. I say "seems" simply because his enthusiasm sometimes gets the better of him, and Darwinism in places comes close to meaning simply "evolution". Ruse knows better, of course, and generally makes the distinction between the notion that all living things are interrelated, and specific ideas (of which Darwinism is one) about how life has evolved, satisfactorily explicit.

Ruse has structured his book rather well. There are five main sections; the first three deal with his view of Darwinism yesterday, today and tomorrow. The first section gives us a brisk account of the man and his main works — with emphasis on Ruse's analysis of the Origin as a three-part essay. "Darwinism Today" tells us of the "coming of Mendelian genetics", what it is and what it means. Part 3, "Darwinism Tomorrow", is an eclectic grab-bag of topics, ranging from the "origin of life" to the "challenge from palaeontology". By this stage the reader will have no difficulty in predicting Ruse's line of argument. Those areas of contemporary biology stressing adaptive explanations through selection are "good", while he takes a dim view of disciplines and ideas which seem, somehow, to diminish the central role of adaptation. Thus sociobiology is "good", but punctuated equilibrium theory has the malodorous air of yesterday's half-eaten fish and chips. Part 4, "Darwin and Humankind", deals with the notion that Homo sapiens has had an evolutionary history, proclaims human sociobiology as on the side of the angels (if only metaphorically) and says that one should not adduce nasty ethics of the dog-eat-dog

variety just because sociobiology can explain so much of our behavioural history. I found this section, and the twochapter, fifth and final section on creationism, unprepossessing.

The guts of the book lie, appropriately enough, in its middle, in parts two and three. Here Ruse tells us what evolutionary biology really is, and should be, all about. I find it a dismal picture. The approach Ruse advocates is pure storytelling — or, as he himself puts it, continued indulgence in evolutionary biology's "favorite parlor game": concocting plausible scenarios of how the elephant got its trunk, the rhino its wrinkled skin and the giraffe its long neck. To Ruse, we know the mechanism, and it's all just a bunch of clever games applying this mechanism of genetic change to explain literally all manner of evolutionary phenomena.

Most critics of contemporary evolutionary theory, myself included. would agree that natural selection is a deterministic mechanism accounting for generation-by-generation change in gene frequencies within populations. It is even testable, given the appropriate data -which involve gene frequencies and generations. But reducing, say, ammonite evolution to a just-so story with natural selection as the hero is, as Ruse says, nothing but a parlour game. The difference between us is that Ruse thinks this state of affairs is just fine. I think parlour games are fine too — but I still cherish the fantasy that I am doing, or at least am trying to do, science when I'm practising my profession.

Ruse uses analogy and circumstantial evidence as his cornerstone criteria for establishing the validity of scientific ideas. Claiming Darwin used Herschel and Whewell as models, and that analogy and inference were what made science "good" in the 1850s, Ruse (as he does so much throughout the book) in effect argues that what was good enough for Darwin should suffice for us as well. There is little here of the spirit of enquiry. We are not enjoined, for example, to hold our notions lightly, to walk humbly before Mother Nature, ready to modify our schemes should the evidence of our senses not rhyme with our fondest notions.

Nowhere in this single-minded tract is Ruse's dedication to the almighty principle of natural selection better displayed than in his little section on trilobite vision. The mathematically "perfect" shape of phacopid and dalmanitid lenses is, to Ruse, exquisite evidence of the power of natural selection. I confess I cannot fathom the difference between Ruse's argument and the older creationist argument from design: see this organ system; observe its intricacy! Only (God, natural selection) could have fashioned such a marvellous organic machine! There is a difference, of course: God, as a supernatural being, does not belong in science, whereas natural selection patently does. But used in this inappropriate fashion, natural selection

becomes a mere substitute for the Creator. It tells us nothing, really, about trilobite eyes or anything specific or meaningful about how they came into existence.

In short, Ruse is a reductionist - all large-scale evolutionary phenomena are readily explicable in terms of population genetics. But there is more than mere reductionism here: he also dismisses molecular biology, simply because population genetics revealed the contents of Darwin's "black box" of heredity, and molecular biology, Ruse avers, has not changed that one whit. All remains secure. That there are patterns of organization with historical implications emerging from molecular and developmental biology that seem to require their own mechanisms in addition to those of population genetics is missing in Ruse's world view. Indeed, in his reflexively negative reaction to the winds of change, Ruse fails to see that the newer arguments are nearly all additive: natural selection explains changes in gene content and frequency within populations, but more than populations are involved in evolution. Another example: Ruse doesn't even bother to mention the idea that species are individuals - the ontological claim underlying the view that macroevolution

may be something more than just scaled-up microevolution.

Darwin and his ideas need no defence. I agree with Ruse: Darwin was a good scientist. In that spirit I would rather imagine Darwin enjoying the spectacle of biologists vigorously debating his, and descendant, notions over a century after the Origin. Ruse, appropriating Darwin's shade as his alone, seems to think that to question some of Darwin's notions is somehow to impugn the man. So he springs to the defence. It is a clumsy defence, one that certainly does Darwin no credit. As a statement of the nature and effective extent of neo-Darwinism, it is nowhere as good as, say, the September 1978 issue of Scientific American, or any of a number of recent texts. As a book aimed at a general audience, it projects a jolly Alice in Wonderland sort of picture that, I fear, will not do overly much for our collective image in the long run. Darwinism, indeed, the entire field of contemporary evolutionary biology, deserves far better.

Niles Eldredge is at the American Museum of Natural History, New York. His most recent book, The Monkey Business: A Scientist Looks at Creationism, will shortly be published by Washington Square Press.

welcome. Following hard on the heels of

his influential scientific text Macro-

A new paradigm for evolutionary change?

R.D. Martin

The New Evolutionary Timetable: Fossils, Genes and the Origin of Species. By S.M. Stanley. Pp.222. US ISBN 0-465-05013-1; UK ISBN 0-633-7022-8. (Basic Books/Harper & Row: 1982.) \$16.75, £9.50.

IT is, perhaps, appropriate that the centenary of Charles Darwin's death should be approximately marked by renewed controversy over the process of evolutionary change. The latest debate concerns one of the most fundamental features of Darwin's theory of evolution by natural selection - gradual change within individual species populations over time. An alternative interpretation, stated with particular clarity by Eldredge and Gould in a seminal paper published in 19721, is that most evolutionary change occurs when a new species develops (during a "speciation event") and that there is little change subsequent to establishment of a species.

In some circles, at least, replacement of the Darwinian concept of "gradualism" by the new model of evolution by "punctuation" has been hailed as a fully-fledged scientific revolution (a Kuhnian paradigm change). To date, however, the debate has raged largely among academics, and for this reason Steven Stanley's The New Evolutionary Timetable is both timely and

evolution; Pattern and Process (W.H. Freeman, 1979) this new book attempts to present the case in terms understandable to the non-specialist. Stanley achieves his aim with considerable success, carrying the reader along with a style that is at once lively and informative. Penetrating insights abound as the arguments are presented, and frequent touches of wry humour add a special touch. (Any modern biologist struggling for a command of the literature will surely be relieved to learn that Darwin actually possessed an uncut copy of Mendel's monograph on hereditary mechanisms!) Certainly, a reading of this book leaves one with plenty of food for thought, regardless of the correctness of Stanley's own conclusions. This is a particularly productive time for the remodelling of evolutionary theory, and The New Evolutionary Timetable conveys the excitement felt by many biologists involved.

Underlying the concept of punctuated evolution is an undeniable fact derived from recent palaeontological studies: numerous fossil species have been found which exhibit a remarkable degree of stability ("morphological stasis"), over long periods of geological time. It must at once be added that such statis can only be recorded for certain body parts (molar teeth of mammals or shells of molluses, for

¹Eldredge, N. & Gould, S J in *Models in Paleobiology* (ed Schopf, T J.M), 82-115 (Freeman & Cooper, 1972)

example) and it is reductionist to conclude that entire organisms remain unchanged over time. Differential evolution of individual body components (mosaic evolution) is a widely recognized phenomenon and there is, for instance, no indication of stasis at the level of the structural gene. Stanley makes little mention of the substantial literature on molecular evolution, which suggests a hiatus between rates of evolution of single proteins and those of whole organisms. It is all too easy to slip into equating fossilized skeletal parts with entire organisms, and this slip is a recurrent feature of the literature of punctuated evolution. Stanley, for example, asserts that Homo sapiens has undergone almost no bodily change since appearing in Europe some 40,000 years

The second aspect of the punctuational model is rapid evolution during speciation, which is generally assumed to occur in relatively or very small, peripheral populations. Such rapid evolution must, however, be *inferred* from the fossil record and involves the assumption that the fossil record is sufficiently complete to document this process unequivocally. In a few special cases this may be true, but the fossil record as a whole is pitifully inadequate — there is, for example, only one major fossil site recording the occurrence of mammals in the entire African continent for the first 35 million years of the Tertiary. We really

need to have estimates of the relationship between the likely catchment areas of relevant fossil sites and the geographical ranges of equivalent modern species; in the absence of such estimates a reasonable guess is that fossil sampling is in fact extremely patchy.

Nevertheless, the picture now emerging from the fossil record is unsettling, and our ideas of evolutionary processes must undoubtedly progress to account for longterm stasis, at least in individual body parts, in species populations. The question is whether such progress requires no more than healthy readjustment of basic theory or whether the changes which occur during speciation dictate recognition of a radically new process ("quantum speciation" or "macroevolution"). Stanley is convinced that the latter is the case. Perhaps understandably, he does not fix upon a single basic mechanism of "macroevolution". though he does somewhat vaguely implicate chromosomal reshuffling. Everything really hangs on the rapidity with which speciation takes place. Stanley states that he is prepared to envisage thousands of generations as the time-scale for "quantum speciation", and this could well be accommodated within a traditional model of evolutionary change. Stanley feels that the fossil evidence for human evolution provides us with one of the best illustrations of punctuation, yet "thousands of generations" could occupy a considerable proportion of the average geological duration of the hominid species currently recognized. In any case, the situation is far more complex than Stanley suggests, notably in the existence of intermediate forms (see Cronin et al., Nature 292, 113-122). Stanley himself is somewhat unclear about the actual limits of his model as well. He suggests (p.157) that human races ("subspecies") may have arisen by punctuated evolution. Quite apart from the fact that here he is treading on extremely contentious ground in sociopolitical terms, it is difficult to see what 'quantum'' differences might define the human races in any context relevant to punctuated evolution.

In the absence of a clear model of the mechanism of "quantum speciation", the case for a radically new paradigm remains somewhat unconvincing, as was the case with continental drift prior to the recognition of sea-floor spreading. Stanley devotes a whole chapter to demonstrating that his doubts about conventional theory do not open the door to creationism; but without a clear concept of the mechanism involved in "punctuated evolution" he is unlikely to convince any creationist! Stanley is right to alert the general reader to the surprising new findings of palaeontologists, but he really goes much farther than the present evidence permits.

R.D. Martin is Reader in Physical Anthropology at University College London and Visiting Professor in Zoology at Birkbeck College, University of London.

Two sides of Darwin

A.J. Cain

Darwin. By Jonathan Howard. Pp.101. Hbk ISBN 0-19-287557-4; pbk ISBN 0-19-287556-6. (Oxford University Press: 1982.) Hbk £5.50; pbk £1.25. To be published in the USA later this year. Darwin. By Wilma George. Pp.160. ISBN 0-00-636502-7. (Fontana: 1982.) £1.75.

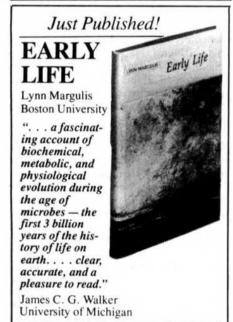

It is a sign of Darwin's relevance that Jonathan Howard's book is in the OUP Past Masters series, Wilma George's in the Fontana Modern Masters. They are nearly identical in their rather nasty format (dirtycoloured paper, undistinguished type-face and over-gorgeous covers, rather like the trash-novels on a railway bookstall), but do not be put off by first appearances - their intellectual content is very good, and both are well worth the money. Both are written by practising zoologists - a refreshing change from so many books on Darwin but zoologists of very different interests. Jonathan Howard is a Principal Scientific Officer at the ARC Institute of Animal Physiology at Babraham, Wilma George is a University Lecturer in the Department of Zoology, Oxford. There is also a useful difference of sex; some of Wilma George's comments on the acceptability of Darwin's theories of sexual selection and male aggression to Victorian men are particularly enlightening.

Jonathan Howard remarks in his preface that

With the centenary of Darwin's death comes a widespread mood of scepticism and unease about the validity and significance of Darwin's contribution to knowledge. The time is certainly right to try to describe Darwin's scientific work briefly and in plain language.

While fully recognizing the importance of Darwin's work for biology, he says "I hope the book is fair in pointing out aspects of Darwin's thinking which lack consistency or have failed to stand up to critical scrutiny". And he rightly emphasizes that whatever others have made of Darwinism in philosophy or sociology, and however true it is that "human life and human society are to a certain extent biological issues", it is Darwin's contribution to biology on which he must stand or fall. "Darwinian philosophy of Darwinian society are post-hoc constructs that had no place in Darwin's thought".

The chapters take us successively through Darwin's life; the foundations of Darwinism; natural selection and the origin of species; the evidence for evolution by natural selection; sex, variation and heredity; man; perfection and progress; Darwinism and ideology; and Darwin as a scientist — an evaluation. The style is mostly good and the exposition clear. Just occasionally it would have benefited from critical reading — for example I can make no sense out of Howard's comment on

"Great resource and beginning reading for the non-specialist who wants to learn about the evolution of early life."

Circle No.03 on Reader Enquiry Card.

Darwin's rejection of Christianity (p.9):

Darwin reserved this uncompromising expression of his religious views for the private autobiography that he wrote for his family. Had he not done so it is inconceivable that T.H. Huxley could have abandoned his war against hypocrisy and helped to carry Darwin's coffin into Westminster Abbey in 1882.

It is inconceivable that Huxley did not know Darwin's views on religion — Darwin was not reticent about them to correspondents — and that he should not have applauded them. Where was the hypocrisy?

Howard's book is essentially a careful exposition and critique of Darwin's arguments in the *Origin* (and in the *Descent of Man* for the evolution of man). It is in the structure of the arguments that he is principally interested. Of course he does not neglect the factual evidence, but produces usually only the minimum of it—for example his comments on the cogency of geological, geographical, taxonomic and embryological information in establishing that evolution had occurred (pp.37–49). Similarly, in summarizing the modern position on natural selection he merely remarks (p.87),

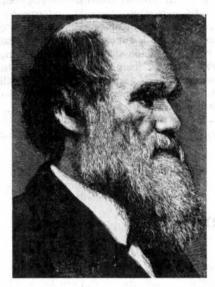

Natural selection and the evolution of natural populations have been observed directly, even in man. There is now no doubt that natural selection is a mechanism of evolutionary change. Whether it is the exclusive mechanism of evolutionary change is still occasionally debated.

And he accepts Darwin's own belief that he had spent too much time on barnacles (p.5) without analysing what he had got from them.

Howard's exposition of ideas and their inter-relatedness is much more full, and he

seems especially interested in predictability and unpredictability and their role in the evolutionary debate. He remarks (p.24):

If mutual competition between organisms was a more important selective influence than mere climatic or geographic change, then the direction of evolution of a species or of an interacting group of species, became effectively impossible to determine.

And, after a supporting quotation from the *Origin*.

It is important to recognise this instance for what it is, namely a hypothetical scenario for fluctuations in frequency of different kinds of organisms that are all subtly related to each other, initiated by introducing into a dynamic equilibrium a single small change....

Here is the physiologist pre-adapted for seizing the complexities of a dynamic system and comprehending the modes (and pitfalls) of its analysis — a valuable approach.

Wilma George's book, written in a particularly attractive and lively style, inevitably covers much of the same ground but is effectively complementary to Howard's in its mode of treatment. She has travelled extensively, realizing the facts of natural history, adaptation and biogeography at first hand - an equally valuable approach. She uses all of Darwin's works very effectively, showing how his interests grew on a wide front, and provides the best short account that I know of just why he was so interested in barnacles, what he got from them and how the ideas acquired led on to later interests (polymorphism, sexuality, insectivorous plants and the fertilization of orchids, for example). Her insight into the development of his ideas on coral reefs in relation to other geological ideas is particularly clearly expressed, and she relates Darwin most effectively to other workers before, at the time, and after. She gives a more concrete exposition of subsequent work in population genetics, natural selection and speciation, than does Howard.

Either book can be read with pleasure by itself; the two combined make a first-class introduction to the subject. Both authors make suggestions for further reading, to which should be added Dorothy Nelkin's spine-chiller Science Textbook Controversies and the Politics of Equal Time, published by MIT Press in 1977. Both glance at the present situation in evolutionary thought, and both expatiate on the forces of unreason, but neither, it seems to me, appreciates just how powerful and dangerous they are. Nelkin's book is a necessary addition.

A.J. Cain is Derby Professor of Zoology at the University of Liverpool.

One foot in sea, and one on shore . . .

D.R. Newth

The Aquatic Ape: A Theory of Human Evolution. By Elaine Morgan. Pp.168. ISBN 0-285-62509-8. (Souvenir Press, London: 1982.) £7.95. To be published in the USA later this year by Stein & Day.

Sigh no more, ladies, sigh no more, Men were deceivers ever; One foot in sea, and one on shore, To one thing constant never.

ONE of the few changes made by Darwin in preparing the second edition of the *Origin of Species* was the exclusion, in obedience to Lyell, of any reference to the "secondary whale". The evolution of aquatic mammals still presents troubling problems, but at least, for the most part, those mammals taking to water do not appear to have had second thoughts. It was, therefore, brave of Alister Hardy to

suggest, nearly a quarter of a century ago, that mankind had passed through a semiaquatic phase and that some of our less easily explained biological features were its legacy.

Hardy laid stress upon our relative hairlessness - and upon the orientation of the hairs that we do possess, upon bipedalism, upon subcutaneous fat, upon our ability to swim, and upon the form and sensitivity of the human hand. All seemed to make sense as adaptations to littoral life, less aquatic than that of present-day otters, but one sufficiently dependent upon shallow waters to make the transition to bipedal locomotion easier to envisage in view of the buoyancy enjoyed by the wading anthropoid. Although Hardy did not attract much support for his idea he was content to wait for the matter to be decided by the fossil precursors of the australopithecines when their discovery should fill the late Miocene-early Pliocene gap in the story.

In bringing us, with Sir Alister's blessing, an extended statement of the case for his ideas, Mrs Morgan adds arguments of her own. She sees in face-to-face copulation an important behaviour pattern shared by mankind and many aquatic mammals, but not seen in infra-human primates. Emotional weeping is another such behaviour. She also believes that speech as a mode of communication may have evolved as the limitations of smell and sight in an aquatic environment made themselves felt. In this, and in the suggestion that underwater childbirth may once have been the norm, she seems to envisage a more completely aquatic phase than Hardy originally did.

The additional arguments do not, I think, greatly strengthen the case. Mrs Morgan herself sees face-to-face copulation in mankind as a consequence of bipedalism and hence, at most, as a secondary consequence of an aquatic phase. On the shedding of tears the position is not simple. While seals and sea

otters apparently weep for emotional reasons as do we, so too do Indian elephants. Elephants like whales have, however, reduced their lachrymal gland and increased the Harderian gland contribution to tears. Mrs Morgan is willing to accept elephants as fellow travellers to the water and back, on this and other grounds, but until we are more confident about the functions of copious tear production it seems best to be cautious.

However the fossil record will doubtless have the final say, and it is becoming yearly more complete. Mrs Morgan re-publishes the suggestion of another supporter of the Hardy hypothesis, L.P. La Lumiere. He believes that the aquatic phase was experienced during early Pliocene times on the coast of the Red Sea. At a time of presumed deforestation, changes in land

and water levels providentially provided an island refuge. La Lumiere offers precise predictions of where the missing links will be found.

This book is written for a lay public and is too brief, and too superficial, to satisfy a serious critic. The bibliography, for example, fails to include many of the authorities referred to in the text. The book is also marred by occasional carelessness—I had to read one passage several times to extract from it a meaning other than that women and sirenians were alone in having two pectoral mammary glands. But the writing is lively and enthusiastic and it will surely engage the interest of those for whom it was written.

D.R. Newth was formerly Regius Professor of Zoology in the University of Glasgow.

A cycle ride to Stockholm

M.F. Perutz

Reminiscences and Reflections. By Hans Krebs in collaboration with Anne Martin. Pp.250. ISBN 0-19-854702-1. (Oxford University Press: 1982.) £12.50, \$19.95.

On 14 December 1932 the dean of the medical faculty of the University of Freiburg, Professor E. Rehn, reported to the Ministry of Education,

As an assistant physician Dr Krebs has shown not only outstanding scientific ability, but also unusual human qualities. His . . . paper on the synthesis of urea in the animal body . . . will be regarded as one of the classics of medical research

Four months later, shortly after Hitler seized power, this same dean sent him a "Notification of Immediate Removal from Office", obediently implementing the Minister's orders against members of the Jewish race.

Krebs kept several such letters and also various press cuttings from those days and had them reproduced as facsimiles in his book. There is the "Manifesto Against the UN-German Spirit" published by the Freiburg Student Union and posted in the University: "Our most dangerous adversary is the Jew and he who serves him. The Jew can think only as a Jew. If he writes German he lies. The German who writes German, but thinks un-German is a traitor . . . ". The Rector of the University, von Möllendorf, ordered the posters to be removed, whereupon the Minister replaced him by the existentialist philosopher Martin Heidegger who endorsed them and proclaimed, "German students! . . . Your existence must not be ruled by learned axioms and ideas Only the Fuhrer himself constitutes today's and tomorrow's reality and law. Daily and hourly must you fortify your faithful

obedience ...'. Most of Krebs's colleagues acquiesced, but one Dr Arthur Jores dared send his and Krebs's former Jewish chief, by then in New York, a reprint with a personal dedication. The envelope was opened by a Nazi colleague who denounced him. Jores was dismissed from his post, publicly branded as an enemy of his country and, in due course, imprisoned.

Despite these harrowing experiences and the extermination of 20 of his relatives Krebs does not follow the example of Einstein who refused ever to set foot in Germany again, but declares in the book that "to be anti-German seems to me just as bad as being anti-semitic". After the War he therefore persuaded the Biochemical Society to re-establish contact with Germany by inviting several known anti-Nazis to the First International Congress of Biochemistry at Cambridge.

Krebs's discovery of the ornithine cycle of urea synthesis had caught the eye of F. Gowland Hopkins, then Professor of Biochemistry at Cambridge and President of the Royal Society. When he heard of Krebs's dismissal, he immediately invited him to Cambridge. The Rockefeller Foundation which had already supported Krebs's research at Freiburg, provided the money, and continued to support his research for the next 30 years. Krebs was deeply touched by the warmth of his reception at the Biochemistry Department at Cambridge and by the generous hospitality and friendliness of English people generally. His book is permeated by affection for England, which he epitomizes by Carl Zuckmayer's, another refugee's, saying that "home is not where a man is born but where he wants to die".

How Prussian Krebs remained all the same! He writes,

... I expected a lot from my associates — hard disciplined work and the ability to accept my criticisms . . . I have tried to be fair; honest and helpful, and not to demand more of others than I do of myself We criticised each other ruthlessly — we knew it was done honestly, in good faith and in a spirit of helpfulness.

Few Englishmen would write such solemn stuff about themselves. I cannot imagine Francis Crick declaring in his memoirs that he demolished my cherished 1949 model of haemoglobin, "honestly, in good faith and in a spirit of helpfulness", rather than admitting to a certain mischievous satisfaction at the dastardly deed.

For people who complain that money for research has become hard to come by. Krebs's early career makes salutary reading. His father, a doctor in Hildesheim, had to support him throughout his medical studies. After graduating Krebs wanted to do research. but paid research posts were rare, never advertised and obtainable only by what used to be known in my native Vienna as Protektion, which signified a mix of sycophancy, nepotism and the old boy network. Eventually Krebs found an unpaid post at the Third Medical Clinic in Berlin where another biochemist who later made his name, Bruno Mendel, became one of his colleagues. One night the Mendels were invited to the Einsteins when Otto Warburg was among the guests. When Warburg told Mendel that he was looking for a collaborator, Mendel recommended Krebs and also raised the money privately to pay him a modest salary. Krebs regards his four years with Warburg as formative for his career and expresses the greatest admiration for Warburg's scientific genius, regardless of his despotic, egotistical and sometimes malicious behaviour, his lack of confidence in Krebs's own talent and his refusal to help him find a university post where Krebs would have to attach himself "to some old ass of a professor". Only in medicine would Krebs be able to make a living, Warburg told him. Warburg demanded of his staff that they work punctually from eight to six, six days a week, a precept which Krebs himself seems to have followed for much of his life. At 11 o'clock on the Monday morning after reading of Warburg's Draconian regime, I walked into my own biochemistry laboratory to find that only one of my three collaborators had arrived yet. "The other two were still working when I left at midnight", the first reported. This convinced me again that the free coming and going of Cambridge is more conducive to dedicated research than the iron discipline of old Berlin.

Krebs made his first great discovery, the ornithine cycle of urea synthesis, in 1931 and 1932. He used the tissue slice and manometric techniques which Warburg had taught him; another decisive factor was his own invention of the Krebs-Ringer

solution. I found it exciting to read of his groping in the dark, methodically testing all conceivable intermediates until he discovered that "one molecule of ornithine could bring about the formation of more than twenty molecules of urea, provided that ammonia was present". From that moment the tracing of the other intermediates followed logical steps. It was the first biological process in which the intermediates were found to play a purely catalytic role. Krebs made this fundamental discovery while in charge of a medical ward with over 40 beds, which makes his feat even more remarkable.

Krebs's unravelling of the citric acid cycle in 1937 was to win him even greater fame, but his letter to *Nature* announcing it was rejected by the editor, Sir Richard Gregory, who at that time took it upon himself to judge the scientific worth of most of the communications sent to him. (It is not known whether Krebs's paper was refereed, but that seems unlikely — Ed.)

Objections were raised at first against both the cycles. Those against the ornithine cycle were later found to be based either on wrong experiments or incorrect interpretation, while those against the precise chemistry of the citric acid cycle seemed fundamental. Biochemists argued that radioactively labelled CO₂ introduced into the cycle should become randomly distributed among the two carboxyl groups of α-ketoglutaric acid, an intermediate two steps after citric acid, because an enzyme would not be able to distinguish between the two symmetry-related carboxyl groups of citric acid. In fact, only the carboxyl nearest to the keto group of a-ketoglutaric acid was found to be labelled; hence, it was concluded, citric acid could not be an intermediate in the Krebs cycle. That was in 1941. I would have been desperate if an apparently valid objection had been made to my most fundamental discovery in which I could detect no flaw, but Krebs writes as though it had never cost him any sleep. Was he really so placid that he did not continuously turn over in his mind all conceivable explanations of the paradox, or did the sunshine of his later glory dissolve the memory of the seven clouded years that were to elapse before A. Ogston, in a brief and classic note to Nature, pointed out the fallacy in the objection: a symmetric molecule attaching itself to an enzyme at three points may give rise to only one of two possible asymmetrical reaction products. This was the birth of the concept of prochirality.

The glory was first heralded in October 1952 by eager journalists who told Krebs that he would shortly be awarded the Nobel Prize, but the rumours proved false and S.W. Waksman received it instead. Krebs relates proudly that the rumours left him and his wife unruffled. But did they really? Nine years later similar rumours about John Kendrew and me were floating

Scherzo metabolico cantabile

Thomas A. Scott

The Biochemists' Songbook. By Harold Baum. Pp.62. Pbk ISBN 0-08-027370-X. (Pergamon: 1982.) £2.45, \$4.95.

How refreshing, in the 1980s, to find a professor of biochemistry writing, not a solemn research text, but humorous biochemical verses. Thirteen important topics of biochemistry have been rendered by Professor Baum into light-hearted songs and set to appropriate popular tunes with piano accompaniment. The biochemical accuracy of the outrageous doggerel can be checked at a glance, because each song appears with the conventional scheme or account.

According to the author, all the songs were written while travelling on the top deck of a No. 22 bus; this I do not believe. He also points out that they are intended for communal singing, ideally with a blood alcohol level of 35 mg per cent; this I do believe. Some of the scansions are tortuous and not always immediately obvious. While the alcohol will not make them any easier, it will stop you worrying whether you get them right.

Perhaps the greatest challenge is in the first verse of "Protein Biosynthesis":

Introns and exons, changes post-transcriptional, and all Glycosylations, don't alter such basics at all

to the tune of My Bonny Lies Over the Ocean. In contrast other compositions have a reassuring and earthy quality, for instance:

If you gobble tagliatelli, Chicken soup with vermicelli, You'll acquire a sagging belly —

are the opening lines of "Fatty Acid Biosynthesis" set to Men of Harlech.

Surprisingly, the author has failed to exploit the rousing coda of Macnamara's Band in "The Pentose Phosphate Shunt". Admittedly, this loud and rasping interlude is normally left to the trombones, but it is tailor-made for Professor Baum's particular style of ethanolic chorus; in the second edition perhaps? Also, these days, when so many bar pianists are over forty, and all the young wags play the guitar, this already excellent songbook might be made more usable by the younger generation by the inclusion of harmony frets or chord names for each tune.

The Biochemists' Songbook is dedicated jointly to Sir Hans Krebs on his eightieth birthday and to the author's wife. Sir Hans has also contributed a foreword, and there is a certain poignancy in the publication of the Songbook so shortly after his death. His cycle is set to Waltzing Matilda, and this year the International Congress of Biochemistry will be held in Australia, where it is no novelty, indeed it is a long established tradition, to sing this tune communally and with a blood alcohol level rather in excess of that recommended by Professor Baum.

Thomas Scott is Senior Lecturer in Biochemistry at Leeds University.

around our laboratory. We doubted them until my secretary rushed in, flourishing two telegrams, one addressed to Kendrew and the other to me. This was it. When we had eagerly torn them open we found them to be from the Pontifical Academy in Rome, enquiring how many reprints we wanted of the papers we had read there the previous autumn. We also pretended to a stoic calm. Unruffled or not, Krebs did receive the Prize the following year.

After nearly 20 happy years and the founding of a flourishing school of biochemistry at Sheffield, Krebs became

Professor of Biochemistry at Oxford and stayed there until his death last November. I was surprised by his statement that Oxford had remained in the forefront of learning for 600 years. Had he never read Edward Gibbons's description of its decline into sloth in the eighteenth century when dons could not even be bothered to teach their students? The picture of Oxford University in Krebs's own time conjured up in the book is of a citadel of unjust privileges jealously guarded by the Party members. Krebs got himself elected to the Central Committee by the under-

privileged Solidarity of Active Researchers, but all his brave attempts to reform The System were defeated by the strength and cunning of the Old Guard, who even went so far as to refuse money offered by the University Grants Committee for the creation of additional science professorships, lest this should lead to the appointment of more Dissidents and Enemies of the Party like Krebs. Despite these rebuffs, Krebs describes his life at Oxford as a happy and successful one. Asked once for a guiding motto, Krebs replied "Never put off till tomorrow what you can do today", which sounds like one of those recipes for virtue Victorian children were made to embroider and hang over their beds. The King of France says it less prosaically in All's Well that Ends.

Let's take the instant by the forward top; For we are old, and on our quick'st decrees, The inaudible and noiseless foot of time Steals ere we can effect them.

Krebs emerges from this book as a dynamic scientist and an engaging, warm-hearted individual utterly devoted to his research and teaching. He quotes Noel Coward's saying that "work is fun, there is no fun like work". I agree.

M.F. Perutz is a Member of the Medical Research Council Laboratory of Molecular Biology, Cambridge. With John Kendrew he was winner of the Nobel Prize for Chemistry in 1962.

AN ENUMERATION OF THE FLOWERING PLANTS OF NEPAL

Vol.1 Gymnospermae & Monocotyledones. H. Hara, W.T. Stearn & L.H.J. Williams. June 1978. **£22.50**

Vol.2 Dicotyledones I. H. Hara & L.H.J. Williams.

June 1979.

£22.50

Vol.3 Dicotyledones II. H. Hara, A.O Chater & L.H.J. Williams. May 1982. £32.00

The publication of the third volume completes this joint project of the British Museum (Natural History) and the University of Tokyo. It is based on the extensive botanical exploration of Nepal by British and Japanese scientists during the last 25 years.

Professors, parasites and public health

Anthony C. Allison

New Guinea Tapeworms and Jewish Grandmothers: Tales of Parasites and People. By Robert S. Desowitz. Pp.224. ISBN 0-393-01474-6. (W.W. Norton:1981.) \$12.95, £8.75.

DURING the period following the Second World War, a few pioneers of a particular type flourished. They were motivated by curiosity about medical problems in primitive societies, the people themselves and how social organization affects health. In an era of liberal funding they were able to spend a great deal of time travelling to New Guinea, South-East Asia, the Australian outback, East and West Africa and other appealing places, collecting thousands of samples of blood, brains and other materials. For some time they were regarded as amusing, if somewhat irresponsible, amateurs, who should settle down and do serious research in Bethesda or London. But they enjoyed themselves, satisfied their curiosity and carried out research of real quality, sometimes solving problems that had for decades defied frontal attack in the United States and Western Europe.

Carleton Gaidusek transmitted kuru, a degenerative disease of the central nervous system, from cannibals of the New Guinea highlands to chimpanzees. His energy and vision played a large part in development of the concept of slow viruses. Baruch Blumberg found that certain sera of North Americans who had received blood transfusions precipitated a component in the sera of some Australian aborigines. Out of this seemingly trivial observation came the identification of hepatitis B virus and the development of a test that has nearly eliminated post-transfusion hepatitis in the United States and Western Europe. Both of these developments won Nobel prizes. Following Denis Burkitt's observations on the prevalence of a particular type of lymphoma in Uganda and other East African countries, Tony Epstein identified in the lymphoma cells the herpesvirus that bears his name. This was found to transform human lymphocytes, to cause infectious mononucleosis and to be associated with a type of cancer of the nasopharynx common in parts of East Africa and China. It is the first likely candidate for a human cancer-inducing virus. The identification of the single amino-acid substitution in sickle-cell haemoglobin, and the demonstration that this gene confers resistance to malaria, were notable contributions to molecular and population genetics.

Included in this group of individualists is Bob Desowitz. After an orthodox training in tropical medicine, he worked on sleeping sickness in Nigeria and on various parasitic diseases in Singapore. He then became Professor of Tropical Medicine in Hawaii, and has travelled as a consultant for the World Health Organization and national governments to New Guinea, Indonesia, Burma and other places. This is a life that many might envy, and its highlights are recounted in this book of essays. Although the title might seem flippant, the book is instructive and entertaining.

Desowitz has a clear and readable prose style. Most medical students and biologists are bored by the life cycles of parasites. It helps to know that the fish tapeworm Diphyllobothrium latum was introduced into the fish of the lake region of Minnesota and Wisconsin by Scandinavian fishermen and was not killed during the delicate cooking of gefilte fish by New York grandmothers. The book is packed with easily assimilated information about parasites. Desowitz is an amusing raconteur and enjoys the detective side of public health, such as finding that a common brain infection among the Ekari of New Guinea was cysticercosis (tapeworm disease) transmitted by pigs given to the people by President Suharto of Indonesia to sweeten the military occupation.

The two central themes of the book are, first, that man-made ecological-environmental changes have been responsible for perpetuating and intensifying the majority of infectious diseases; and, second, that ultimately effective control of these infections will follow widespread use of the time-honoured, sensible approach of environmental sanitation.

Each of these assertions is open to debate. It is true that building the Aswan high dam in Egypt increased the already high risk of developing schistosomiasis in Egypt, but that has to be balanced against the manifest advantages of building such a dam. Whenever such enterprises are contemplated, the environmental health implications should be considered by international experts convened by the World Health Organization and the Food and Agriculture Organization. Determined efforts should be made to prevent such health problems; this would be a useful way to use international aid funds, which are often squandered.

Does control of disease necessarily require the time-honoured, sensible approach of environmental sanitation? Nobody would argue against sanitation. But with labour and fossil fuel costs escalating, there is no realistic prospect of eliminating malaria from Africa by ditches and drains or tsetse flies by scrub clearance. Despite 30 years of the Chinese "People's War against the Snail" and Chairman Mao's poem "Farewell to the God of Plague", schistosomiasis still exists in China.

It is more realistic to employ whatever

weapons are at hand. Environmental sanitation should be used wherever it is feasible, and coupled with health education. Immunization too, has its place. Smallpox was eliminated by a vaccination campaign carried out with military determination, and immunization markedly reduced the incidence of poliomyelitis in industrialized countries. Chemoprophylaxis and chemotherapy are also useful. They greatly reduced the prevalence of yaws and have protected millions of people and domestic animals from parasites. As in the case of chemoprophylaxis against filariasis in

Samoa, quoted by Desowitz, knowledge of the social organization of the people helped.

The essays of Desowitz provoke these and many other thoughts. They are recommended to students of medicine, public health and biology, to administrators of international health programmes and to those who enjoy a good read about science and the world in which we live.

Tony Allison is Director of the Institute of Biological Sciences at Syntex Research, Palo Alto.

The making of an archaeologist

Colin Renfrew

Mortimer Wheeler: Adventurer in Archaeology. By Jacquetta Hawkes. Pp.416. ISBN 0-297-78056-5. (Weidenfeld & Nicolson: 1982.) £10.95.

"TURNING out of Pall Mall, I was transfixed by the steely gaze of Mr. Augustus John. 'Hullo, Rikki,' he said; 'still digging?'. 'Hullo, Augustus,' I replied; 'still sketching?'. With these words Sir Mortimer Wheeler (Rik to his friends) began Still Digging, his vivacious autobiography, published by Michael Joseph in 1955. Its subtitle, 'Adventures in Archaeology', is recalled in that of the biography of Jacquetta Hawkes, now published six years after his death.

There is no more equivocal gift to the biographer than a really good autobiography. The freshness and energy of Still Digging make it lively reading today, and its very excellence offers Jacquetta Hawkes something of a challenge, to which she has risen conscientiously and above all sympathetically, making considerable effort to get behind the public persona and reveal the human being.

It is indeed for that persona that Wheeler is still most widely remembered. For those too young to have been viewers, it is difficult to convey the national impact of his charismatic role, back in the 1950s, in that remarkable television programme Animal, Vegetable, Mineral. Both Wheeler and the question master Glyn Daniel became household names — they were elected "TV Personality of the Year" in 1954 and 1955 respectively. This was haute vulgarisation, in Glyn Daniel's term, popularization at its best and with a serious purpose. It made archaeology both better known and more widely understood, laying the foundation

● The third edition of *Digging up Bones* by D.R. Brothwell, published by the British Museum (Natural History) and Oxford University Press, appeared earlier this year. Price in paperback is £8.95.

in Britain not only for more substantial subsequent television coverage (the Buried Treasure series, and then Chronicle) but also, it could be argued, for the rapid growth over the past 20 years of archaeology as a degree subject which is numerically strong in a number of universities. As the author stresses here, Wheeler was, in his early excavating days in the 1920s, a pioneer of what today might be called public relations. But of course it was very much more than this: Wheeler saw his discoveries in human, personal terms and he never lost-the gift of catching the imagination of the non-specialist. He saw, too, that if the ultimate aim of archaeology is to inform us about the human past, it is the duty of the academic not only to research but to communicate. As he wrote in his best book, Archaeology from the Earth (Oxford University Press, 1954): "In a simple, direct sense, archaeology is a science that must be lived, must be 'seasoned with humanity'. Dead archaeology is the driest dust that blows".

In his later years, as Secretary of the British Academy, Wheeler made substantial contributions to the development of archaeology in Britain and indeed to the standing of the humanities in general. The British Academy, a much more recent creation than the Royal Society, has even now not quite achieved the active leadership within its own field which its elder sister has among the sciences. That the two are nonetheless at least comparable owes much to Wheeler's leadership during his tenure as Secretary from 1949 to 1968, as Jacquetta Hawkes describes most effectively.

Undoubtedly, however, Wheeler's main claim to lasting fame rests with his work as a pioneer of archaeological field methods. His incisive and systematic approach to the problems of excavation was not entirely new — as he generously acknowledged in the preface to Archaeology from the Earth, many of the methods and principles which he used were derived "from those of the

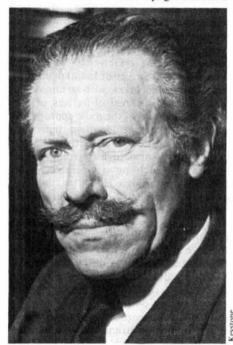

greatest of all archaeological excavators General Pitt Rivers". It was to those largely forgotten publications from the end of the last century that Wheeler turned, and with their aid developed systems of recording, with emphasis upon the interpretation and drawing of stratigraphic sections, which transformed excavation in Britain from a pastime into a discipline.

Wheeler's most personal contribution was an unfailing grasp of what he called the Tactics and Strategy of excavation. Those same qualities which produced a first-class soldier (he rose to the rank of Brigadier in the Second World War and fought at El Alamein) and highly effective administrator (Director General of the Archaeological Survey of India) made him a masterly field worker, with an unrivalled perception of the real objectives of the work in hand and of the most appropriate measures for their achievement. Indeed, it could be argued that with Wheeler excavation became to archaeology what experiment is to the physical sciences — the opportunity through clear thinking and careful planning to try out new ideas and to test old ones. Of course British archaeology overseas had other pioneers of field method besides Wheeler - Sir Flinders Petrie, as Wheeler himself acknowledged, or Sir Leonard Woolley or Sir Max Mallowan. But Wheeler was the unflagging advocate of sound field method as the essential basis of further work, and his teaching in the years after the First World. War promoted in Britain an awareness of stratigraphic principles which persists today and is ultimately sounder and more productive than the metrical thoroughness of the German school or the statistical enthusiasm of the American.

Jacquetta Hawkes does not perhaps evaluate as highly as she might this particular achievement, although she describes Wheeler's individual excavations fully and well. It deserves to be set in a wider context. For it would be quite possible to see Wheeler's keen sense of problem in fieldwork as anticipating in some respects the deliberately problem-orientated approaches of the "New Archaeology", which grew up in the last decade of Wheeler's life. It is not the inclination of either approach to set great store on facts just for their own sake. Both see the aim of fieldwork as the verification or testing of hypotheses through the gathering of fresh material, and recognize that it is ideas and problems which should determine the excavation strategy. This clear sense of priorities makes Archaeology from the Earth an inspiring introduction to fieldwork; still the best introduction, in my view, although many new techniques have been introduced over the past 30; years. And while the author rightly stresses Wheeler's ability to imagine and bring to life the people behind the archaeological record, his encouragement of the technical specialisms of archaeological science whether conservation or radiocarbon

dating — and his recognition of their place within a more disciplined approach are at least as important.

The author's emphasis is perhaps a more personal one, although she copes well and expertly (being an archaeologist herself) with Wheeler's excavations and research. She is concerned to see Wheeler as a person, dealing as much with the private life (and many loves) as with the public achievement. She begins: "Mortimer Wheeler will rise from these pages as a Hero

Mortimer Wheeler — creator of a discipline.

figure. Of that I feel sure even as I write the very first words of my book". Certainly the remarkably varied career - yet singleminded in its devotion to archaeology — is admirably told. Her earlier chapters and description of the war years inevitably owe a great deal to the autobiography. But surprisingly, perhaps, it is the portrait of Rik Wheeler in his old age, as he is remembered by many today (including myself) which seems the most compelling, indeed moving. Those same qualities of panache, of awareness of the effect of the moment, which may have raised evebrows (and indeed aroused some enmities) earlier, and which caught the attention of millions of viewers in the 1950s, made him the most splendidly vivacious good company in his seventies and eighties, and a friend and encouragement to many half a century younger than he. They come over well in this affectionate portrait.

Wheeler came to archaeology with a military briskness of mind which helped him to make the subject, in the scientific as well as the organizational meaning of the term, a discipline. Perhaps just as important, he brought with him a zest and a gusto which made it, in a real and un-trivial sense, entertaining.

Colin Renfrew is Disney Professor of Archaeology at the University of Cambridge.

Grounds for doubting the pessimists

P. D. Henderson

The Ultimate Resource. By Julian L. Simon. Pp.412. US ISBN 0-691-09389-X; UK ISBN 0-85520-440-0. (Princeton University Press/Martin Robertson:1981.) \$14.50, £9.50.

WRITING in 1933, Keynes said of Malthus's Essay on the Principle of Population that "it attracted immediate attention, and the warfare of pamphlets instantly commenced... which for 135 years has never ceased". Hostilities have continued during the half-century since Keynes wrote, and Julian Simon's new 400-page volume is a reminder that not only pamphlets are involved. The issues that Malthus raised so provocatively in 1798 are still live, unsettled and highly contentious.

The main issues are two: first, the extent to which it is possible for human societies to achieve material progress; and second, the effects of population changes on their prospects of doing so. In relation to these, it is still possible to think of the main battleline as drawn between Malthusians and anti-Malthusians, though as in other spheres of conflict there are wide differences of view within each of the two factions.

Following in the steps of the master, modern Malthusians are pessimistic on both issues, or at least inclined to emphasize dangers and limitations rather than opportunities. As to material progress, the possibilities for growth in output are seen as restricted in any given society, and for the human race as a whole, because of constraints on the availability of land or natural resources. From this arises the threat of overpopulation. It is admitted that population growth will create a larger labour force - more hands, as well as more mouths - and thus tend to raise the level of potential output; but given the constraints imposed by nature, not much can be expected from this positive effect. Thus higher rates of population growth will often be a drag on material progress. Conversely, lower population growth may hold the key to sustainable prosperity.

By contrast, anti-Malthusians take a more sanguine view. They are sceptical about limits to growth, while at the same time many of them stress the positive effects of population increase on a society's capacity to produce goods and services. These are the two main themes of Simon's interesting and readable book. The author pours scorn on current pessimism and prophecies of doom — despite one or two favourable references to Malthus himself — and the book may be described as a scholarly polemic.

Most of the argument is directed to the two issues identified above. Part One ("Towards Our Beautiful Resource Future") considers the possible scarcity of natural resources, and deals successively with minerals, food supplies, land, energy,

environmental pollution and conservation. On all of these Simon points out, with some well chosen and carefully presented statistics, that the evidence of recent decades is more encouraging than is generally realized. Thus minerals, food products and energy supplies have over the past century become less costly in relation to wages; world food supplies have grown more rapidly than population; while the expectation of life, which he regards as the best single indicator of pollution, has risen all over the world. In Simon's judgement, all these favourable trends are likely to be maintained into the indefinite future: in the case of the cost of raw materials, he makes an engaging offer to back his assessment with money, by accepting bets from readers who take a different view. He thus rejects completely the notion that economic growth is constrained by the availability or cost of resources.

Part Two is mainly concerned with the effects of population growth on average income per head. In most of the economiccum-demographic models that have been developed over the past 20 to 30 years, these effects are unfavourable, largely because it is assumed that with more children in the average family the rate of saving and capital accumulation will be lower, and that a higher proportion of capital investment will go towards duplication of facilities (more schools, for example), rather than increasing capital per head. As against this, Simon makes three main points. First, larger families may increase the willingness of individuals to save and invest. Second, there are likely to be significant gains from economies of scale, since total output will be higher. Third and most important, output per head will benefit from "the contribution of additional people to our stock of useful knowledge" (p.196): a larger population means not only more mouths and hands, but also more brains. His broad conclusion, which he argues is consistent with the facts of economic history, is that moderate as distinct from zero rates of population growth are likely to have favourable effects on income per head, at any rate in the longer run, in rich and poor countries alike.

In Part Three ("Beyond the Data") the argument is taken further than the issue of material progress alone, and other values are brought in. Simon holds that enabling an extra person to live and enjoy life has value in itself, and that the well-being of a society has to be defined with reference not just to the average standard of living of its members, but to their total numbers also. He makes a sharp attack on the values and assumptions of anti-natalist bodies, such as Planned Parenthood, and argues that there is no justification for trying to reduce rates of population growth, as distinct

from enabling parents to obtain the size of families that they would wish.

Throughout the book Simon's own position, as summarized just above, is contrasted with the latter-day Malthusians whom he wishes to discredit. There are numerous quotations, some from learned articles and monographs, but most from popular books, newspaper articles and advertisements, designed to illustrate the whole range of contemporary pessimism. The style is kept deliberately informal and colloquial, while the author's convictions are often set out in a highly personal way. Now and then this mode of presentation becomes a little trying, but in general the argument is clearly and effectively conveyed, without either condescension or oversimplification. In view of the range and complexity of the topics that are covered, this is a considerable feat.

In judging the merits of Simon's argument, two distinct tests are relevant, corresponding to the two aims which the book tries simultaneously to achieve. The first aim is destructive: to undermine and cast doubt on current neo-Malthusian pessimism. The second is to offer an alternative view of the world, an acceptable analysis of events, relationships and trends. Not surprisingly perhaps, the author succeeds more completely with the former task than with the latter.

. The process of demolition is carried out with skill and resource. In part, the prophets of doom are discredited by the various excerpts from their own works, many of which make sorry reading. But the main weight of the argument rests on the evidence of the past and on general economic reasoning, both of which are often neglected or undervalued by the pessimists, and which the author presents extremely well. Unfortunately, the views that he attacks are widely held and influential. By challenging them so effectively Simon has performed a real service.

When it comes to his alternative view of the world, there is more room for doubt. At a number of points the argument seems to me to be too unqualified or incautious, while in some respects it is less complete than it should be. For example, his generally admirable discussion of natural resources is marred by a failure to consider the possibility that oil is a special case. Because of what are often presented as facts of geology, it may be that the period of cheap oil was a historical accident, a bonanza which cannot be repeated. If this is so, and given the unique convenience and properties of petroleum as a fuel, a secular rise in the real price of oil is not at all to be ruled out; and it is insufficient to dismiss the increases of the 1970s, as Simon does, as being due simply to the machinations of OPEC. Moreover, because of its role in the world economy, and the uneven distribution of productive capacity and reserves, the effects of oil price increases are potentially much more damaging than in the case of other raw materials. Simon does not go into this, and his two chapters on energy are superficial.

As to population, a clearer distinction could have been made between two aspects of the question: the absolute size of a population, and its rate of growth. More space should also have been given to two arguments against rapid population growth: one is the possible congestion arising from higher densities, while the other is that a rapidly growing labour force may lead to a more unequal distribution of income. Again, Simon states correctly that a judgement on the net advantages of population growth may depend on how one weighs more distant costs and benefits in relation to those which are nearer in time. But he says nothing about how this valuation of time should be made, nor about the suitability of using for this purpose the actual rates of interest that are established in financial markets.

More worrying is an occasional tendency to rather serious overstatement. Thus in the concluding chapter, we are told that "The standard of living has risen along with the size of the world's population since the beginning of recorded time" (p.345). This is false. One can find phases of history — as for example in England from the mid-thirteenth century till around the end of the seventeenth — when a rise in population is thought to have led directly to a fall in real wages, and vice versa: the simple Malthusian model seems to fit the facts. It is probably only in the modern era that this inverse connection has been broken, first in the industrial countries and more recently in other parts of the world: possibly it holds good even now in some of the poorest and least developed countries. Here and at some other points of the argument, Simon has yielded to temptation: he makes overconfident generalizations about relationships that are subject to considerable variety and change.

Despite these reservations, the book is much to be recommended. It is possibly the best available modern treatment of the issues that Malthus raised.

The hunting of the rorqual

Arthur Bourne

The History of Modern Whaling. By J.N. Tønnessen and A.O. Johnsen. Pp.798. UK ISBN 0-905838-23-8; US ISBN 0-520-03973-4. (C. Hurst, London/University of California Press: 1982.) £22.50, \$45.

THE POPULAR image of whaling as the harpooneer, lance in hand, standing bravely on the prow of a row-boat ready to do battle with Leviathan, is enshrined in the writings of authors like Melville and Bullen. The picture is a romantic one but, as both those writers knew, whaling was far from romantic. It was — and its rump is — a tough business, firmly based on hard commercial interests. If there is little romance in whaling, as compensation there is a world of fascination and of no period is this more true than when the new whaling industry was emerging from the old.

The modern epoch really began in February 1864 when a small steam-powered vessel, the Speset Fides, sailed out of Tønsberg in south-eastern Norway for the whaling grounds off Finnmark. It is the story of the unfolding of that modern history which is the subject of Den Moderne Hvalfangsts Historie, of which the volume under review is a much-condensed English translation. In it the authors have cleverly drawn together the strands of the technical, sociological and financial developments of that period.

The birth of the modern whaling industry will always be associated with one man, the owner and skipper of the Spes et

Fides, Svend Foyn. Why he was to be the leading force and why Norway should have been the birthplace are interesting questions. As the authors show, the Americans dominated the old whaling scene and were experimenting with new methods at the same time as Foyn. Even his idea of combining an explosive harpoon fired from a cannon mounted on a steampowered boat was not original, and he was not the first man to realize that the future of whaling lay in the chasing, catching and processing of the great rorquals. The real answers to those questions lie not only in the technical inventiveness of the various contenders - of which there were many but also in the social and economic changes that were occurring at the time.

In the middle of the nineteenth century the Americans were looking increasingly inwards. The opening of the West with its vast prairies and potentially enormous mineral wealth seduced capital and labour away from the coast and the sea. In Norway the situation was very different. With little hinterland and an increasing population which the nation's industry and agriculture could not sustain, thousands of Norwegians, in common with many other Europeans, sought their futures in North America. By one of those quirks of fate, America's retreat from the sea opened up an opportunity for the Norwegians left at home. They were quick to fill the gap, and, combined with the expansion of sea-trade generally, this provided the stimulus for the growth in Norway's maritime industry.

At the same time the economics of whaling were propelling technical developments along parallel lines in several countries. The stocks of right whales -"right" because they were slow swimmers and floated when killed - had been so decimated by the middle of the century that they were unable to support a viable industry. The interest of the whalers turned to the rorquals which "teemed in the seas", but which were too swift for the row-boats and, moreover, sank when killed. One of the first to experiment with explosive harpoons was the American T.W. Roys. who invented a harpoon-throwing gun and set out to see "if a cargo of oil could be obtained from whales previously unavailable to mankind". There were other innovators and other developments, one of which was, the authors believe, of decisive importance to Foyn's own ideas. This was the grenade harpoon invented by George Welch in 1867, three years before Foyn's final patent was granted. In many countries similar inventiveness was displayed, but Foyn was the most persistent. He believed in the potential of the rorqual fishery even during his experiments with the Spes et Fides when failures lost him money, he kept going. He was in the end the right man at the right time.

The first of the rorqual stocks to follow the right whales to extinction was, not surprisingly, the Finnmark stock. From then on it was for the whaling companies a matter of geographical expansion and greater sophistication in techniques and ship design. The whalers extended their activities to wherever rorquals could be found and eventually to the waters surrounding the Antarctic continent. It was there that the greatest harvests were to be culled, and where the technical ingenuity of the whalers was again stretched.

The problems were to stay at sea long enough to justify the cost of fitting out a fleet, and to build more powerful and faster catchers. The floating whalefactory, heralding the pelagic whaling industry, extended the range of the catchers, and the introduction of offloading the oil into tankers enabled the fleets to remain at sea for months. From 1937 and the launching of the Japanesebuilt Seki Maru, the catchers became progressively more powerful. However, no matter how long the whalers were on the oceans, nor how sophisticated their equipment, if the whales were not there they could not be caught. Inevitably the Finnmark story was to be repeated again and again, and nation after nation, including Norway, had to abandon pelagic whaling - political ingenuity in conserving whale stocks fell far short of the technical expertise in destroying them.

The whaling industry is neglected by the student of the development of the industrial nations and yet it reflects the social and economic conditions of the times most vividly. It also provides clear insight into the way those conditions forced men to seek means of utilizing resources that had hitherto been out of reach. The story of the whaling industry shows too how difficult it is to maintain an industry based on natural resources, even renewable resources, if immediate commercial considerations over-ride the long-term benefits of rational exploitation and investment.

The authors of this book have achieved a remarkable piece of condensation and R.I.

Christophersen must be congratulated on a fine translation. The only sad thing about this volume is that it is unlikely that we shall ever see an English-language version of the original four-volume work — and that it is equally unlikely that mankind will learn from the mistakes it so amply documents.

Arthur Bourne was an observer at the International Whaling Commission from 1964 to 1968. His great-grandfather was a contemporary and competitor of Svend Foyn.

Cartography: from astrolabe to orbiter

Helen Wallis

The Mapmakers. By John Noble Wilford. Pp.414. UK ISBN 0-86245-041-1; US ISBN 0-394-46194-0. (Junction Books/Knopf: 1982.) £9.95, \$20.

A NOTABLE theme in the history of human endeavour is the record of man's survey and mapping of the Earth, the Moon and (by spacecraft) of the nearer planets. Even the earliest surviving records show a surprising degree of sophistication in the cartographic arts. Thus an example of early cadastral mapping has been identified in the depiction of a village found in rock carvings of the Valcamonica in northern Italy and dating from the second and first millennia BC. The Babylonian world map of about 500 BC is one of the earliest depictions of the cosmos. And two silk maps recently recovered from the Ming tombs show the advanced level reached by the Chinese in the second century BC

With the development of the geographical sciences in classical Greece, the coordinate system for the mapping of the world was established which is still the accepted method today. Even in the so-called "dark ages" of Europe, a continuing tradition can be traced from the surveys of the late Roman empire through mediaeval times.

The European Renaissance brought about a revolution in mapmaking. The newly invented techniques of engraving made possible the "exactly repeatable picture", and in the late fifteenth century led to the establishment of the mapmaker's craft and the map publishing industry. At the same time European ventures of exploration set in motion the mapping and surveying of the world. A comparable revolution has taken place in the past 50 years with the development of aerial surveys, automated cartography, and mapping from and in space.

The history of the complicated processes involved in these developments can be told in various ways. The role of the mapmakers themselves is often subordinated to the record of the artefacts, the atlases, maps and globes. John Noble Wilford in his new history of cartography sets out to correct this bias. In The Mapmakers he tells the story of "the multitude of diverse characters", ranging from scholars and scientists to clockmakers, schoolteachers and spies, aviators and technicians, who stand out in the history of cartography. Although he has not spent a lifetime working with maps as such, his professional post as science correspondent for The New York Times makes him well qualified to identify the pioneers and innovators in the history and explains his concern to bring out the drama of personal triumph. As professional mapmakers normally write their reports in "the bloodless language of the specialized

Surveyors at work in the eighteenth century — detail from a map of Warwickshire by Henry Beighton, 1728.

journals", he supplements written sources for modern surveying with interviews with the practitioners themselves, at NASA, the ÚS National Geodetic Survey and so on.

No single volume on the history of cartography can be comprehensive. It is important therefore to note that Wilford's book is really a history of the attempts to measure, survey and map the Earth, the Moon and the planets. The definition of cartography implied in this treatment is that of the United Nations, therefore, and not that of the International Cartographic Association (which excludes survey from its terms of reference). What is particularly valuable is the integration of the historical and the modern. Most histories of mapmaking end in 1900 or earlier, and leave to others the recording of recent developments. Thus the first two parts of the book deal with the broad trends and signal achievements of cartography and geodesy prior to the twentieth century. The final two parts include some earlier history but are focused on the twentieth century.

Another, less welcome, aspect of the treatment is an evident "Western" bias. Like many other histories, the book is "ethno-centred" (to quote the current term), dealing largely with the achievements of Mediterranean and European peoples. Arab geographers such as Idrisi, for example, are conspicuous by their absence, and the remarkable achievements of Chinese cartographers appear only in the pages dealing with the maps from the Ming tombs. In so focusing the story Wilford follows Lloyd, A. Brown, whose Story of Maps (Little, Brown; 1949) provided the classic account of mapmaking to 1800. The similarity in treatment and in the selection of illustrations for the early period explains why some parts of Wilford's book (for example, the sections on the Cassinis and John Harrison) will seem almost familiar to those well acquainted with Brown. Wilford's detailed account of the survey and mapping of India and North America extends the compass, however, in addition to the fact that the time span covered by Wilford is much greater.

The book is illustrated by reproductions of some of the most important maps and by photographs, but documentation of the illustrations is inadequate. The Babylonian world map (p.11), for example, is in the British Museum, not the New York Public Library (p.415), as the reader might suppose from the credits. Sources for information in the text are, for the most part, not cited, but bibliographical notes are provided for each chapter.

In general, however, Wilford's Mapmakers can be warmly recommended as an essential addition to library reference shelves, and as an excellent introduction to mapmaking past and present for geographers and map lovers alike.

Helen Wallis is Map Librarian at The British Library, London.

Ancient woods in modern times

John Andrews

Woodland Conservation and Management. By G.F. Peterken. Pp.328. ISBN 0-412-12820-9. (Chapman & Hall: 1981.) £25, \$49.95. Ancient Woodland: Its History, Vegetation and Uses in England. By Oliver Rackham. Pp.402. ISBN 0-7131-2723-6. (Edward Arnold/University Park Press: 1981.) £50, \$99.95.

DURING the past 30 years, more ancient mature woodland has been destroyed in Britain than in the preceding four centuries. The direct cause of this has been the parsimonious attitude of post-War government towards forestry and a corresponding benevolence to agriculture, with an increasingly phoney system of cost-benefit appraisal favouring overproduction from farming while squeezing forestry into short-rotation, softwood monocultures whose main product is pulp.

It is a tribute to the Forestry Commission's technical skill that it has succeeded in developing techniques of wood production under uniquely difficult conditions in the uplands, but no credit to foresters in general that they have fostered the destruction of Britain's remaining native woodlands, both by encouraging their replacement by conifers and by meekly acceding to their conversion to farmland. Perhaps conservationists too must share the blame, for failing to protest sooner and louder: not least the Nature Conservancy Council which should lead the movement, and yet still shies away from producing a policy on forestry after nearly a decade of indecision.

Fortunately, many NCC staff are a good deal harder-nosed than their politically-appointed Council. Woodland Conservation and Management is written by George Peterken, a member of NCC's scientific team, and ventures some provocative views. Thus,

private landowners, who enjoy a disproportionately large share of national wealth, should be prepared to bear a disproportionately large share of the sacrifices needed to provide national needs for amenity and nature conservation. Indeed, the continued political acceptability of private landowning may depend on recognising these and other public responsibilities

— a view gaining currency among conservationists patronizingly advised to leave protection of the countryside to the good will of the landowning community.

The book, however, is primarily a scientific work. It commences by examining the origins, management and ecological characteristics of British woodland, demonstrating the special value of ancient, primary woodland to a wide range of species which have persisted in such sites — and nowhere else — despite many centuries, perhaps in some cases several millennia, of human management.

The second part of the work considers the types of semi-natural woodland, their classification and management. Woodland classification in Britain is still bedevilled by the lack of a generally accepted system and here the effort is made to present one for use by any competent naturalist or forester. Such a classification has an important practical value, providing the basis for identification of woodland sites of similar type so that comparative conservation and management judgements can be made.

About a third of the book is devoted specifically to woodland nature conservation. There is much helpful advice on the recording and assessment of woodlands and on management methods, both where conservation takes priority and where the first objective is production. Though the emphasis is on native woodlands, the pros, cons and opportunities presented by the new conifer forests in the uplands are not neglected.

The book is well and economically written. Though some sections are technically complex, it contains much of general interest, not least a clear and concise statement of the objectives and priorities of nature conservation - matters' on which many foresters and some naturalists seem confused or misinformed. However, as an ornithologist, I must regret the author's heavy botanical bias: though birds have great powers of dispersal, many survive best in ancient woodland; and the absence of any reference to Britain's only endemic bird - the Scottish crossbill, which appears to be largely confined to Caledonian pine forest — cannot be lightly. forgiven.

In Ancient Woodland, Oliver Rackham, approaches the subject from a different standpoint. In the author's words, the main theme is

the self-renewal typical of English woodland history: the quiet, usually unremarked regrowth of the young shoots, automatically replacing the woods every time they were cut down, decade after decade and century after century.

But it is more than that. Dr Rackham's special skill lies in unravelling man's relationship with woodlands and, in scholarly yet entertaining style, he deduces from them aspects of rural social history since pre-Roman times.

Though the book contains examples from many parts of England and the Continent, it is based largely on the author's own studies in East Anglia. This region is a splendid study area, containing an unusual variety of woods which have been well documented — paradoxically the outcome of early clearance which meant that the remainder assumed special importance for local use and was systematically conserved until recent years.

Roughly the first quarter of the book covers woodland classification, soils, plant and tree communities; in some measure this overlaps with Peterken but the emphasis on man's role in shaping the woods gives a usefully different slant. Evidence from pollen analysis, soil structure, earthworks and archaeological remains, vegetation and tree rings, oral tradition, paintings and written records is brought together to present woodlands not only as places of beauty, rich in wildlife, but also as a part of our heritage - as much a reflection of past human skills, aspirations and shifts of power as any cathedral.

Moving on to the human uses of woods, the author leads us from Neolithic times through the extensive records of Domesday to

the mad world of the 1970s, in which the price of ordinary oak-trees is as low, in relation to the

value of money, as at any time since the fifteenth century; the price of oak *timber* is higher, again in relative terms, than at any time in history; and prices paid for underwood, provided the seller knows where to find the buyer, seem to be roughly equal to the previous all-time maximum in the eighteenth century.

Nearly half of the text deals with individual tree species, examining their distribution, prehistory and history, modern ecology and conservation. With many references to specific sites, one is presented with the opportunity to go and see for oneself — a temptation I will certainly find irresistible when the sun shines, just as dipping into the book will be a continuing pleasure on rainy days.

John Andrews is Head of Conservation Planning at the Royal Society for the Protection of Birds, Sandy, Bedfordshire. that heart disease hardly occurred in Roseto, Pennsylvania, while the inhabitants maintained a cohesive. conservative society, although they ate a typical Western diet. Wolf himself in Social Environment and Health (University of Washington Press, 1981) views disease as maladaptation to changing social conditions. Inglis concludes that it is therefore wrong to treat disease by orthodox methods. He proceeds to select the failures of modern health care and to ignore all the successes. He would have us believe that all heart surgery is a wasted resource, that no cancer patients benefit from chemotherapy, that mental hospitals should be abolished and that immunization plays little role in preventing infectious diseases. He states that "the net value of orthodox medical treatment is far less than it was twenty-five years ago, and is declining".

The chapters I find most objectionable. no doubt because they deal with my own subjects of study, are on infectious diseases and on cancer. Inglis dismisses research into the identification and control of infectious agents in disease (for example in Legionnaires' disease and in malaria) as "mechanistic heresy" obscuring psychosocial elements. He also shows a remarkable prejudice against virologists. imagining that they narrowly pursue infectious organisms without reference to epidemiology and pathogenesis. Elsewhere he supposes that virologists have sought to monopolize cancer research, preventing immunologists investigating "cancer immunotherapy", whereas it is the virus-induced cancers that may yield first to immunological means of prevention or therapy. The eradication of smallpox, the resounding medical triumph of the 1970s, is not cited at all in Inglis's book, yet its success depended on the very combination of preventive vaccination and thorough epidemiological investigation that orthodox medicine provided where 2,000 years of ayurvedic methods in India failed. The successful outcome of virological research leading to immunization against poliomyelitis earns a grudging mention, with the extraordinary suggestion that the rare but devastating neurological damage caused by polio virus infection is more related to psychosocial stress than to the virulence of the virus strain. Polio and infectious mononucleosis are two particularly intriguing diseases of civilization in that children of the higher social classes are the ones most at risk; the epidemiological factors underlying this phenomenon are not probed by Inglis, presumably because they do not fit his view of how virologists conduct research.

Inglis's criticisms of orthodox cancer treatment resemble those which have recently occupied the columns of the Washington Post and the diatribe by Dick Richards (The Topic of Cancer: When the Killing Has to Stop; Pergamon, 1982) against those who "cut, burn and poison"

The malaise of modern medicine?

Robin Weiss

The Diseases of Civilisation. By Brian Inglis. Pp.371. ISBN 0-340-21717-0. (Hodder & Stoughton: 1981.) £10.95.

BRIAN Inglis is a respected journalist and author who has written several informative books on the history of medical practice, orthodox, homeopathic and supernatural. His latest, The Diseases of Civilisation, is subtitled "An indictment of traditional methods of medical treatment and a plea for a completely new approach". Inglis surveys the major diseases affecting the Western world today - heart disease, cancer, mental illness, common infections, "auto-immune" and degenerative diseases - and concludes that modern medical science and practice has failed to live up to the high hopes of the immediate post-War period. Rather than question how realistic these expectations ever were, generated by journalists like himself as much as by the medical profession, Inglis concludes that the medical establishment is to blame for the intractability of ill-health in modern times. He depicts the medical profession as a self-perpetuating oligarchy composed of too many narrow specialities which dominates medical education and research, distorting both to serve its own ends and thereby obstructing public health. The food, tobacco and pharmaceutical industries are the accomplices in this medical crime, abetted by Governments that shy away from confrontation with an entrenched medico-industrial complex. Inglis argues that this unholy alliance has prevented the medical profession from embracing and acting upon discoveries of the important roles of diet, stress and other social factors in the causation of disease, so that resources which should be channelled into primary health care are deflected into the ever-increasing expense of high technology hospital treatment.

Much of this argument is regrettably only too true. The medical establishment is extremely conservative and profoundly suspicious of social or "unorthodox" approaches to disease. As Thomas McKeown has long argued, medical education is almost entirely geared to the treatment of acute illness as presented in teaching hospitals; the underlying causes of disease, other than specific pathogens, receive scant attention and the very concept of health is hardly raised during the training of doctors. Governments faced with butter mountains and tobacco revenues usually duck environmental and health issues when confronted by powerful lobbies - witness President Carter dismissing Mr Califano from the Department of Health, Education and Welfare, and Mrs Thatcher reshuffling Sir George Young out of the Department of Health and Social Security as soon as they tried to take significant action on curbing the promotion of cigarette consumption.

Brian Inglis has tackled a most important subject — the limitations and misconceptions in the modern Western approach to illness and health — yet I find his book disappointing and his message pernicious. Posing as a carefully researched documentary, it is more a polemical tract in the tradition of Ivan Illich's *Medical Nemesis* in which Inglis overstates his case to the point of being anti-science. His main thesis is that psychosocial stress is not taken into account in the investigation, management and prevention of diseases of civilization. He cites Stewart Wolf's important finding

cancer patients. Few would deny that patients sometimes receive excessive or inappropriate treatment; but having berated specialities, Inglis does not see that this is most likely to happen when cancer patients are treated by non-specialists. Inglis blames the medical establishment for the lack of progress in treating cancers of the lung and breast. Yet he makes no reference whatsoever to the successful treatment and cure of many paediatric cancers and leukaemia, Hodgkin's disease, choriocarcinoma or testicular cancer, which all result from the development of the aggressive forms of therapy which he so derides. True, these are rare types of cancer in terms of total incidence of malignant disease; but they are major causes of serious illness in children and young adults, with a high social and personal toll. There are common cancers too — of the skin, for example — for which diagnosis at an early stage undoubtedly reduces mortality very significantly. Inglis also entirely ignores palliative treatment, assuming that surgery, radiotherapy, chemotherapy or endocrine treatment invariably cause more suffering than leaving the cancer patient untreated by orthodox methods.

Inglis's account of cancer research funding policy is also seriously misinformed. He states that because the British cancer research charities "are largely controlled by specialists, naturally they favour projects which help them in their hospital work, providing them with better-equipped operating theatres, improved radiotherapy machines, more powerful drugs". This is nonsense, as no research project is more difficult to obtain funding for than one that smacks of a medical service role. Following the British Medical Journal's peculiar outburst two years ago, Inglis reiterates that less than 2 per cent of the British charities' expenditure is directed towards research into cancer epidemiology and prevention, an absurd underestimate even if one discounts the potential of basic research for future prevention. He thinks the public should be given more opportunity to influence the way in which cancer research funds are spent. This is a laudable sentiment, though difficult to implement;

Handlist for historians

The Science Museum, London, has recently published a vade-mecum for science historians, Reference Books for the Historian of Science: A Handlist. The bibliography has been compiled by S.A. Jayawardene with the intention of providing a volume to complement other bibliographic manuals, covering the primary and secondary sources of the history of science, by the inclusion of general reference books. The handlist includes some 1,000 titles, and is available from Library Publications, Science Museum Library, South Kensington, London SW7 5NH, price £2 50, £3 by post

moreover, "the public" will almost always choose to fund high-technology hardware, such as CT scanners, in preference to research into the psychosocial aspects of cancer that Inglis rightly wishes to promote.

In criticizing the medical management of the mental patient Inglis is on stronger ground, in that no single orthodoxy has emerged. From his account one does have the feeling that the theory and practice of treatment for mental illness has not advanced beyond the blood-letting era. Having heaped scorn upon the medical establishment's "obsession with diagnosis" for infectious diseases, Inglis here deplores the unreliable classification of mental disease, quoting large discrepancies between US and British psychiatrists. In fact, the WHO definition of schizophrenia can now be used to standardize diagnosis. As Julian Leff discusses in his recent monograph Psychiatry Around the Globe: A Transcultural View (for review see p.523), the incidence of schizophrenia is surprisingly uniform across different cultures, though its recognition as a disease state requiring treatment differs widely.

Inglis misses another opportunity for serious debate in his chapter on iatrogenic disorders. Quoting the Hippocratic dictum "At least, do no harm", he does not discuss whether the harm induced by treatment might be less than that of no treatment. Inglis justly reproaches the medical profession over drug abuse and carefree prescription, particularly in treating the symptoms of diseases of civilization without paying due attention to underlying causes. Yet in an earlier chapter he criticizes by-pass surgery for angina pectoris when chronic drug treatment might achieve the same result. One of the most notorious examples of iatrogenic disease (not quoted by Inglis) was the induction of leukaemia in patients treated with X-irradiation for ankylosing spondylitis. The radiotherapy undoubtedly caused enormous relief from the symptoms of a crippling, painful and eventually fatal hereditary disease; given the prospect of that relief, with the possibility of dying from iatrogenic leukaemia 15 years later, would Inglis have advised the spondylitis patient to spurn treatment?

Overall, Inglis has broached an important topic by questioning the basis of our current medical philosophy and its disregard for preventative health measures and social care. But I wish that he had not chosen to present orthodox medicine and research as the antithesis of genuine care and that he had researched his commentary more deeply. More importantly, I earnestly hope that any young man with testicular cancer or parent with a child suffering from leukaemia will not refuse orthodox treatment as a result of reading this book.

Robin Weiss is Director of the Institute for Cancer Research, London.

Politics of pesticides

M.S. Swaminathan

Circle of Poison: Pesticides and People in a Hungry World. By David Weir and Mark Schapiro. Pp.99. ISBN 0-935028-09-9. (Institute for Food and Development Policy/Third World Publications: 1981.) \$3.95, £2.50.

Circle of Poison provides an insight into the process by which "someone in the underdeveloped countries is poisoned by pesticides every minute". The circle begins with the activities of leading multi-national corporations which dominate the sevenbillion-dollar-a-year pesticide market. The links in the chain include loopholes in government regulations in the United States, the import policies of developing countries and the indifference of bilateral and multilateral donors, regional and international banks and UN agencies.

Weir and Schapiro argue their case cogently. For example they point out that at least 25 per cent of US pesticide exports are products that are banned, heavily restricted or have never been registered for use in the United States - "The Federal Insecticide, Fungicide and Rodenticide Act explicitly states that banned or unregistered pesticides are legal for export". Developing countries which receive hazardous pesticides recommend the application of such pesticides in a routine manner, partly due to ignorance and partly due to their being cheaper than less-toxic products. An instance has been cited where parathion is being used in Central America at a dosage 40 per cent greater than necessary. In contrast, through the adoption of better pest-management procedures, US farmers now use 35-50 per cent less insecticide than ten years ago, with no adverse effect on crop yield. An important consequence of the indiscriminate use of pesticides is the multiplication of pesticide-resistant insect species, leading to the use of still higher concentrations of the chemical, and so on.

At each stage in the process, the circle of poison has its victims - the staff in pesticide manufacturing plants, those who load and unload the chemicals, Third World peasants, workers and consumers, and finally everyone else in the world who eats food contaminated with pesticide residues. But undoubtedly the greatest impact is felt in the developing nations. According to some calculations, the rate of pesticide poisoning in such countries is more than 13 times that in the USA. The authors give examples from their investigations in Mexico, Central America, Pakistan, Indonesia and Papua New Guinea to illustrate how pesticides prohibited in the US reach the peasants of the Third World. Unfortunately, in these countries there are neither enough scientists to investigate the dangers arising from such pesticides nor is there a wellinformed and well-equipped government machinery to prevent foreign pesticide makers from selling products which are banned in their home countries.

However the United States and other pesticide exporters also suffer the consequences of the dumping of banned chemicals in developing countries. According to the US Food and Drug Administration, about 10 per cent of the food items imported into the United States contain higher levels of pesticides than are permitted. Therefore, even on the basis of enlightened self-interest, it would be advisable for developed countries not to permit the export of chemicals which cannot be sold at home.

The authors also question the pathway of productivity improvement involved in "the green revolution strategy". By encouraging monoculture, losing genetic diversity and not promoting integrated pest-management schedules, the use of large quantities of pesticides has become essential. The authors suspect that the emphasis on this kind of high-yield technology is largely because of the interests of the multi-nationals — several of them are involved not only in the production and sale of pesticides, but also in the production and distribution of seeds and chemical fertilizers.

The circle of poison has become possible only because of a circle of collusion between national and international companies, banks and government and UN agencies; all playing a role in the spread of poisonous chemicals. Fortunately, in recent years, some steps have been made towards breaking the unholy triple alliance of pesticide manufacturers, importers and finance institutions. The authors propose several methods by which the fight against the proliferation of hazardous pesticides can be brought to a successful end. Action, they say, has to be taken both at national and international, and individual and institutional levels. Examples are cited of the kinds of effective checks being developed in the Philippines and Malaysia. The resolution of the United Nations General Assembly passed in December 1979, urging member states to exchange information on hazardous chemicals (and pharmaceuticals) that have been banned in their countries, and to discourage export of those products to other countries, is another move in the right direction. This has been followed by similar steps by OECD and other organizations. The Environmental Protection Agency in the USA is also becoming more vigilant.

David Weir and Mark Schapiro have rendered signal service by drawing attention to the deficiencies in existing regulations and practices in the trade of hazardous pesticides in both the exporting and importing countries. The book, therefore, deserves to be widely read by all connected with agricultural research and development as well as those involved in the development of public policies relating

to human health and environmental protection. Nonetheless, their account does have some flaws.

In the section entitled "More Food and Yet More Hunger", the authors try to place the blame for rural poverty mainly on developments in the improvement of agricultural production. This is not wholly correct since it is now widely accepted that the new technology involving the cultivation of management-responsive varieties is neutral to scale with regard to the size of the farm in which the technology is adopted. Hence, a small farm is not a handicap from the point of view of adoption of new technology. A small farmer, however, has many problems arising from the cost, risk and return structure of farming. The potential offered by a small farm for intensive agriculture can, therefore; be realized only by removing the constraints faced by small farmers. The action required is in the realm of public policy and not technology. Technology can only help to maximize

output from the resource endowments of each country; poverty can be minimized only through appropriate political decisions in the fields of land and livestock reform, asset transfer and social security. Unfortunately, terms such as "miracle seeds" have created the impression that new technologies can provide miraculous solutions to problems of poverty, social inequality and injustice. It would have been prudent to have avoided the temptation of making a few casual and over-simplified statements on rich-poor equations, since such problems deserve in-depth analysis. This would have lent greater authority and credibility to the principal message of the book — that the temptation to make profit out of poverty and ignorance can be countered only through widespread awareness of the techniques used for this purpose.

M.S. Swaminathan is Director General of the International Rice Research Institute, Manila, Philippines.

Whence the power of the medicine-man?

Robert Ubell

The Clay Pedestal: A Re-examination of the Doctor-Patient Relationship. By Thomas Preston. Pp.226. ISBN 0-914842-68-4. (Madrona: 1981.) \$12.95.

THOMAS Preston, the author of this book on modern medical practice in the United States, is a cardiologist with his heart in the right place. Acutely aware of the way doctors play musical chairs with their patients, he rises to their defence, sympathizing with the patients, castigating the physicians.

Preston's analysis closely follows much of what many of us already know from sad experience. Divorced from their patients, concentrating on their business, toying with medical technology, doctors often alienate the sick and frightened with impoverishing bills, high-handed manners and bureaucratic mazes. He lays the blame for these failures on elite training at medical schools, authoritative and paternalistic attitudes, and the advantages of power, prestige and money. Arrogant doctors, he claims, frequently act decisively when hesitation and doubt are best; often they perform no better than quacks and faith-healers.

From greed, doctors tend to over-treat and over-test:

When a surgeon is faced with a choice between doing nothing for which he collects a thirty-dollar consulting fee, and recommending surgery for which he would get three thousand dollars, is he not going to be influenced in the direction of surgery? Only a physician would dare suggest impartiality under the circumstances.

Preston cites studies showing that Americans who come to their doctors for help are twice as likely to undergo surgery as their British cousins. Since the overall mortality rate in the two countries is roughly the same, either Americans are more prone to illness - which seems unlikely — or a vast number of pointless operations are being performed. And because of over-medication and useless therapies, many patients become ill some even die - because they visited their doctor. Had some stayed away, allowing healing to take its natural course, they would have remained alive and well, unharmed by iatrogenic disease.

Preston's most cutting attack is against doctors who practice medicine as if it were a guessing game, relying solely on their subjective clinical judgement rather than proven scientific methods. The random, controlled trial is the only sound basis on which doctors can claim effective therapies; yet physicians continue to walk down unscientific paths. Preston shows that medicine without science is doomed to repeat its recent and dangerous errors radical mastectomy, chelation treatment for arteriosclerosis, pure oxygen for premature babies, electroshock therapy for mental illness: Ironically, it was under the banner of improved scientific standards that physicians campaigned for and ultimately won control over the practice of medicine in the United States.

Presson draws parallels between American doctors today and ancient healers, taking us back to tribal communities where the shaman and the primitive medicine-man dispensed their arts. He tries to show us how in fundamental ways medical practice has remained unchanged for millennia, that the basic needs of patients and the old ways of practising medicine emerge as a natural consequence of social interaction. He argues that unless patients rise up and fight for their rights, doctors, who always have had the upper hand, will continue to exercise unreasonable control.

His argument from history is, however, sketchy and flawed. Anthropologists tell us that healers in tribal societies did quite different things in different cultures for their sick and dying. Levi-Strauss reports that the "shaman" in one society may act the self-conscious charlatan, reaping the rewards of power and prestige; in another, the healer may be someone who merely happens to know tribal lore. Moving on, Preston also forgets to inform us that mediaeval barbers and surgeons practised their trades in the same guild. Nor does he tell us that, until modern times, surgeons and chefs were in the same fraternity in the British navy. What bound the cooks, barbers and surgeons was not their natural social standing, but their knives and scissors — or perhaps the fact that food. hair and disease have always been and will always be with us.

By making us believe that the doctorpatient relationship is a natural feature of the human landscape, Preston stumbles and falls into the same myth-making apparatus that holds us all in its thrall. While he makes some recommendations for reform, he fails to see how he has adopted the same myths that have helped American doctors secure their power and privilege.

Preston would have been a better guide had he not turned the pages of his history book so far back. In the nineteenth century, American physicians practised alongside homeopaths, midwives and assorted fakers and purveyors of patent medicine. It was not until the early days of this century that doctors, under the political leadership of the American Medical Association, codified their position and under the slogans of standardization and faith in science, systematically excluded all but those who emerged from approved medical schools and who gained access to practice by passing state licensing exams (also controlled by the AMA and its local societies). By the 1920s, the AMA had established a complete monopoly over the practice of medicine in the United States.

In The Clay Pedestal, Thomas Preston has tackled a subject which demands close and critical scrutiny. But an analysis of medicine that merely reflects what patients already feel about their doctors, and neglects to tell them how doctors gained their power, says a lot about what we already know and nothing about what we do not.

Robert Ubell is the American Publisher of Nature.

Around the world of mental illness

G. Morris Carstairs

Psychiatry Around The Globe: A Transcultural View. By Julian Leff. Pp.204. ISBN 0-8247-1532-2. (Dekker: 1981.) SwFr. 58.

This conspectus of mental illness "around the globe" has many of the attributes of those luxury cruises in which travellers combine the pleasures of exotic sight-seeing with those of being instructed by experts about what they have seen. Dr Leff is an admirable tour guide. He handles statistics with respect but is always ready to point out their limitations as well as their contributions to knowledge. As befits an epidemiologist, he first scrutinizes the methodology of any survey and only then discusses its findings.

His global tour de l'horizon is clearly presented, under four major headings: (i) Do psychiatric conditions look the same in different countries? (ii) Do psychiatric conditions have 'the same frequency in different countries? (iii) Are psychiatric conditions treated differently in different countries? (iv) Do psychiatric conditions have a different course in different countries?

These four parts are followed by a final section discussing the mental health of immigrants in general, and of West Indian and Asian immigrants in Britain in particular. He gives us interesting summaries of research findings in each of these areas of inquiry. From start to finish one basic question keeps recurring, namely: if multiple culture-specific factors enter into the perception, treatment and outcome of psychiatric illnesses, then how meaningful is it to make cross-cultural comparisons of these illnesses?

There is now ample evidence that both organic and functional psychoses can be identified in every society; but even in respect of these major illnesses we have to proceed cautiously in interpreting symptoms in the same way as we would do in the West. As Leff puts it: "It is clear that delusions and hallucinations, the main symptoms of psychotic illness, can only be judged as present in relation to the patient's cultural milieu". This still leaves us uncertain as to just how such symptoms are to be evaluated.

A large part of this book is thus devoted to demonstrating ways in which the procedures of psychiatric diagnosis are being made more valid and reliable than they have been in the past. An interesting example is the US/UK Project which had its origin in an observation of the biostatistician, Morton Kramer. He pointed out that, if their respective data were to be believed, then the first admission rates for manic depressive psychoses in the age group 55 to 64 were twenty times higher in Britain than in the USA. Could this really be true?

In order to put the question to the test it was necessary to construct an objective, systematic interview schedule and to train a team of six psychiatrists (four British and two American) in its use. The instrument chosen was Professor John Wing's Present State Examination (PSE). The team used it to ascertain the "project diagnosis" for consecutive series of patients admitted to hospitals serving London and New York. When they did so, the previously wide discrepancies in diagnoses became very much reduced. Analysis of the results showed that hospital doctors in New York were accustomed to use a much wider, concept of schizophrenia than that used in London, as a result of which they included under the label of schizophrenia many patients who would be diagnosed as manicdepressive in London.

This was the first international use of the PSE. Its next major deployment was in the WHO-sponsored International Pilot Study of Schizophrenia (IPSS) in which teams in nine countries (the USA, Britain, Colombia, Czechoslovakia, Denmark, India, Nigeria, Russia and Taiwan) collaborated in collecting cohorts of patients who met certain defined criteria, assessing them in terms of the PSE and then following them up for a period of five years. Here the PSE could be used in its original form only in Britain and the USA; in each of the seven other countries it had to be translated into the local language.

This international study (which still continues) has produced some interesting findings; among them, the demonstration that patients with specified "core symptoms" of schizophrenia could be found in every country; and also that the final diagnostic judgements (whose criteria were not laid down) were fairly uniform in seven countries but widely divergent in the other two, namely the USA and Russia, In. the former, a cultural emphasis on Freudian concepts led to a wide concept of schizophrenia so that many cases were included under this heading which would not be so regarded in the other countries. In Russia, diagnostic practice was — and still dominated by Professor Snezhnevsky's theory that schizophrenia presents in three forms, much attention being paid to the postulated course of the disease. Many patients were diagnosed as schizophrenic because although they did not yet show major symptoms it was predicted that they would eventually do so.

Dr Leff is candid about the large obstacles which hinder cross-cultural agreement about certain of the symptoms of mental illness, particularly in the neuroses. He devotes a chapter to discussing "The language of emotion", pointing out that there are some languages in which there are no single terms for "depression" or "anxiety". In translating

an instrument such as the PSE into Yoruba, for example, recourse has to be made to metaphors in common use such as "the heart is weak", for depression, and "the heart is not at rest", for anxiety. One cannot be sure that these phrases correspond at all precisely with the English words.

Not only are some languages richer than others in the language of emotion: even within cultures members of underprivileged groups may have less well-developed abilities to recognize or to express nuances of feeling (as Basil Bernstein has demonstrated in British society).

Dr Leff is dedicated to the use of standardized instruments, accompanied by glossaries and sets of instructions as the best way to enable different observers to recognize and record symptoms in the same way. Usually he remains keenly aware of the difficulties which still remain, but very occasionally he lapses as when, after completing a review of a number of surveys of psychiatric illness in Asian countries he draws attention to the wide differences in the prevalence rates for neurosis, and comments: "We can infer that the very highest rates found in the Asian surveys are likely to represent the most realistic estimates of the true prevalence of the neuroses".

Normally, he would be the first to question the concept of the "true prevalence" of neuroses. He knows that minor neurotic symptoms are very common in normal subjects. Determining at what levels of frequency and severity these symptoms should constitute an illness is a judgemental decision. Until some less subjective indicator can be found, the prevalence of neuroses can only be measured in terms of stated, hopefully relevant, operational criteria. As yet there is no such thing as the "true prevalence" of neuroses — and perhaps never will be.

The chapters on the mental health of immigrants to the USA and to Britain are interesting not only for their findings (that, in general, immigrants show a high rate of incidence of schizophrenia but that Asian immigrants attend their general practitioners for minor complaints less often than do their British neighbours), but also because they show that useful crosscultural research can now be carried out within the British Isles and USA. One factor, however, appears to have been overlooked. This is Srole et al.'s report, Mental Health in the Metropolis: The Midtown Manhattan Study (McGraw-Hill, 1962), which found very high rates of psychiatric disorders among immigrants but only among poor immigrants. The much smaller number of rich immigrants did not experience an excess of these disorders.

The final chapter tells us, in grim detail, about the many handicaps which an Asian immigrant physician has to contend with in trying to advance his career in a Western country: these are economic, linguistic,

social, educational as well as professional. Having taken a special interest in the welfare of overseas postgraduate students at the Institute of Psychiatry, London, Dr Leff knows what he is talking about; but here he seems to present a totally gloomy picture. Every experience of the immigrant doctor is a negative one, culminating for some in a neurotic or psychotic breakdown, with all their disastrous implications. Is there no gleam of light at all in the experience of our immigrant trainees? Surely we can all remember some exceptions, men and women who have earned the friendship and respect of their British or North American colleagues and have embarked upon an academic or clinical career. Admittedly, they are in the minority. This chapter, although tangential to the rest of the book, will serve a useful purpose by reminding us about the difficult lot of our overseas trainees.

G. Morris Carstairs is currently a Fellow of the Woodrow Wilson Center, Washington DC, and recently spent three years in India as a visiting professor of psychiatry.

Art of insects

J.L. Cloudsley-Thompson

Insects Etc.: An Anthology of Arthropods Featuring A Bounty of Beetles. Pp.108. ISBN 0-933920-25-3. (Hudson Hills: 1981.) \$50.

What is there in common between Edgar Allan Poe, Jonathan Swift and Raoul Hausmann? The answer, immediately revealed by perusal of the literary anthology with which P.A. Gette enlivens this unusual book, is that they were not good observers of insects. Like Salvador Dali's pre-1950 ants, Hausmann's houseflies had only four legs, Swift's were endowed with stings and Poe confused bugs with beetles. Far more observant were Lewis Carroll and Vladimir Nabokov and, of course, Réaumur, Thoreau and Jean-Henri Fabre. Buffon was evidently a careless writer: "The insect is a small animal

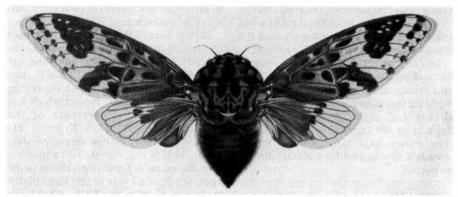

without blood. The latter [sic] can be divided into large and small kinds".

Literary activities, like art, are not necessarily marred by inaccuracy such as this. Less excusable, however, are the errors of nomenclature and spelling apparent in the names of the various arthropods portrayed. For instance, Argiope bruennichi (mis-spelled) is an impressive, striped, orb-web spinner, but it is not the zebra spider. This name has always been reserved for Salticus scenicus the little jumping spider, common on walls and fences throughout Europe, Asia and America. Again, the scorpion is not Buthus occitanus as stated but, unmistakably, Scorpio maurus, the classical "scorpio" of antiquity.

The 34 dazzling, large-format colour plates are taken from photo-realistic paintings by Bernard Durin, without doubt an unusually gifted illustrator in the great tradition of Audubon, Edward Lear and Louis Agassiz Fluertes. Of 33 species illustrated (there is a close-up of the head of Zonocerus variegatus in addition to a painting of the whole grasshopper), 16 are beetles, 5 grasshoppers, 6 Hemiptera, 3 Hymenoptera, a single butterfly (the peacock), a spider and a scorpion. The species depicted are, as might be expected, large, brightly coloured and sometimes bizarre. The paintings illustrating them are breathtaking. Durin is not only a meticulous observer but he really succeeds in creating the illusion of irridescence in his beetles and in making insects' wings look transparent. A commentary on each of the arthropods illustrated, with information about various aspects of its behaviour, life cycle, food, enemies and folklore, is provided by Gerhard Scherer.

Zoologists are often so familiar with the subjects of their research that they overlook obvious questions posed by them. What are the functions of the extraordinary colours of some insects, why do others have such long legs or antennae, what are the advantages and drawbacks of their shapes and sizes? It might be worthwhile taking a second, thoughtful look at the subjects of Durin's paintings.

J.L. Cloudsley-Thompson is Professor of Zoology at Birkbeck College, University of London.

Pycna antinorii, the African cicada, painted by Bernard Durin. Reproduction in black and white and reduction in size do scant justice to the picture.

REVIEW ARTICLE

Mantle metasomatism—continuing chemical change within the Earth

D. K. Bailey

Department of Geology, University of Reading, Whiteknights, Reading RG6 2AB, UK

Mantle fragments carried up from as deep as 200 km by high-velocity eruptions show metasomatic introduction of volatile bearing minerals, before melting. The broad spatial and temporal distribution of alkaline magmatism shows that transfer of lithophile elements to the outer Earth by rising volatiles, is a long-term and continuing process in planetary evolution.

METASOMATISM is a chemical change, whereby a pre-existing mineral or rock is converted to another composition. It usually refers to a solid-state transformation, with material transfer through a vapour or fluid, without melting. Paradoxically it has always found easiest acceptance when applied to lowtemperature and -pressure phenomena, for example, the detailed replacement of calcium carbonate fossils by iron sulphide, or the substitution of plant tissue by silica in fossil wood. Mining geologists have long accepted metasomatism as an important process, giving rise to a whole class of metasomatic or 'replacement' ore bodies, spectacular examples of which are wholesale replacement of limestone beds by metal sulphides¹. Obviously, some evidence of the original material must remain as proof of metasomatism, and with higher temperatures and pressures this becomes more vulnerable. Controversy is most likely when deep metasomatism is proposed as the origin for a relatively common rock such as granite²: the end product is chemically unexceptional, and the issue complicated by rock recrystallization (metamorphism) at high temperatures and pressures. Even so it should be noted that most metamorphic changes are not isochemical because the mineral reactions involve at least volatile losses or gains3.

On a limited scale, metasomatic replacement in crustal rocks is well documented. , new minerals formed including feldspar, tourmaline, kaolin, micas, sulphides, serpentine, carbonates, calc silicates, alkali amphiboles and pyroxenes. All cases involve volatile or mobile elements from the range K, Na, C, H, F, Cl, S and B, and the metasomatic process operates by fluid infiltration or diffusion. The efficacy of processes of this kind is demonstrated by the oxygen isotope equilibration between large rock masses and circulating groundwaters⁷. Nonetheless, as a major rock-forming process in the crust, metasomatism may still be controversial, so that mantle metasomatism (where the evidence is fragmentary) might seem esoteric. The concept arose from the need to integrate geological, petrological and geophysical observations on cratonic alkaline magmatism^{8,9}. This concept was supported by the fact that crustal rocks intruded by alkaline magmas provide perhaps the best examples of alkali metasomatism, now known as 'fenitization' from the type area at Fen (Southern Norway)¹⁰. Subsequently, mantle fragments brought up by alkaline volcanism were found to be metasomatized, such that if melted they would yield the compositions observed as lavas11. Support came from chemical studies on alkaline lavas from oceanic islands, indicating variations in the source mantle that would be explicable by alkali enrichment before melting¹².

Composition of the mantle

The mantle constitutes the major part of the Earth (84% of the volume and 68% of the mass) and is the chemical and energy reservoir driving crustal and lithogenic processes. As most of the information about the mantle, and all below 250 km,

is derived from geophysical observations, the picture that emerges is inevitably smoothed by the limited resolving power of the indirect observations. Furthermore, remote physical measurements are unlikely to discern anything less than gross variations in chemistry (and even then the domains of chemical variations would have to be very large). Consequently there is some danger of treating the Earth's mantle as if it were chemically homogeneous or (perhaps even more dangerous) rendered homogeneous soon after accretion of the proto-Earth. For convenience it is customary to regard the bulk composition of the mantle as being essentially peridotitic (dominantly magnesium-rich silicates, olivines and pyroxenes) similar to the silicate fractions of stony meteorites¹³, particularly the abundant chondrites. Meteorite compositions are widely used as reference standards for minor (trace) elements and isotopes, but the once popular chondrite Earth model has (with some exceptions¹⁴) largely fallen into disfavour¹⁵. An internationally agreed standard for bulk mantle chemistry would have value in general geochemical comparisons, but any chemical reference standards are liable to abuse in the sense that they can all too readily assume the status of a real piece of mantle from which specific surface rocks were derived. Garnet peridotite, as brought to the Earth's surface through diamond pipes, is the preferred choice for a generalized bulk composition 13,16 and although Ringwood prefers, as a geochemical device, to use a hypothetical material, pyrolite, (a chemical mix of peridotite and basalt) he notes that garnet peridotite is "rather similar in composition"15. Beneath this apparent unanimity there is diversity, ranging from the "bulk composition of the mantle is very uncertain" to there is "major element homogeneity throughout the mantle source regions" of basaltic magmas¹⁵ It is, however, largely from the difficulty in explaining the variations in chemistry between magmas that concepts of mantle heterogeneity have grown¹⁷. Some types of heterogeneity go beyond those expected from irreversible changes caused by previous expulsion of melts to the surface, and seem to require additions or mixing of sources earlier in the Earth's history.

Arguments for metasomatic changes in mantle composition fall into two categories—those deduced from chemical characteristics of lavas, and those where there is observed replacement of an earlier mineralogy. Both need to be seen in a geological context. Direct observation has claim to precedence but it is convenient to deal with lava chemistry first, because the case has been developed in the less complex framework of oceanic volcanism, and because the two lines of investigation become most compelling in unison.

Chemical variations in the oceanic mantle

All the evidence for mantle metasomatism is provided by igneous activity, especially mafic (basic) and ultramafic magmatism for which there is abundant evidence of origin at least in the upper mantle, and maybe deeper. As liquid samples from

the mantle; the magmas themselves may be expected to carry some imprint of the source chemistry. Deciphering the imprint depends on simplifying assumptions, some of which may be easily acceptable, but all are debatable. Basic lavas erupted within the ocean basins are generally believed to be uncontaminated by continental crust and surface materials. Because of their voluminous and widespread eruption, mid-ocean ridge basalts (MORB) are taken to be the products of high degrees of melting of the source mantle, and to have many chemical characteristics that are unmodified by subsequent crystal fractionation. Isotope ratios of heavy elements such as Sr, for example, are held to be immune¹⁸⁻²⁰, but all these views have been challenged²¹. Most geochemists working on MORB, however, are satisfied with the assumptions as a working hypothesis, which allow the use of element concentrations, ratios and isotopes to characterize the chemistry of the source mantle. Trace elements that because of their ionic size and charge cannot be accommodated in the crystal lattices of the main peridotite (mantle) minerals are said to be 'incompatible' and hence strongly partitioned into any melt that may form. Using crystal-melt partition coefficients it is possible to calculate expected fractionation patterns of various elements, for different amounts of melting of plausible combinations of mantle minerals. The calculated patterns may then be compared with those observed in MORB. The first attempt gave the best fit for the MORB incompatible element patterns at 15-30% melting of a model mantle peridotite, whereas alkali basalts from oceanic islands seemed to be restricted to as little as 3-7% melting if they were to give the required patterns²². Also the higher concentrations of a range of large ion elements in alkali basalts, compared with MORB, required that the source mantle was richer in these elements than the MORB source²². Gast postulated that the mantle supplying alkali basalts was more primitive, and hence the MORB source had lost some of its large ion elements in an earlier melting episode. He described the MORB source as "depleted" with respect to the supposedly primitive alkali basalt source. Behind this notion of depletion was the knowledge that there is commonly insufficient of the large ion radioactive isotope ⁸⁷Rb in MORB to support the observed amounts of the daughter isotope 87Sr, which is most readily explained by some Rb loss in the earlier history of the mantle source. Subsequently, it became clear that by the same token ocean island alkali basalts had too much Rb for their content of ⁸⁷Sr, and this was consistent with their source having been 'enriched' in large ions some time before eruption²³. In current usage, 'enriched' often means just 'more abundant',

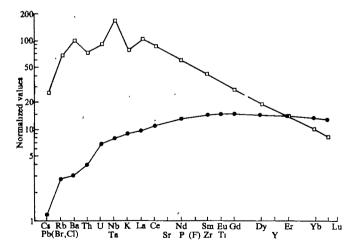

Fig. 1 Comparison of normalized abundance patterns of incompatible elements from alkali basalt (□) (oceanic islands) and midocean ridge tholeiite basalt (●). Adapted from ref. 25. Refractory lithophile elements such as rare earths, Ti, Zr, U and Th normalized against chondritic meteorites. For other normalizing values see ref. 25. Highly alkaline lavas such as nephelinite will in general plot at higher levels than alkali basalt.

and may even start to assume the connotation of 'metasomatized'. Before describing something as 'enriched' or 'depleted' its previous condition must be known. This leads back to the most difficult assumptions, concerning the origin and evolution of the planet. Typical are discussions about rare earth elements in layas, in which the abundances are compared by normalizing against a chondrite meteorite standard. For example, the lower concentrations of the light rare earths (La, Ce, Pr, Nd) in MORB, causing a downward dip in their distribution pattern when normalized against chondrite abundances, may be said to be due to an earlier depletion in the mantle source. Taken alone this conclusion can only be based on an expectation that an undepleted mantle source would provide liquids with light rare earth distributions similar to, or higher than in chondrites: either way, assumptions have been made about the source, and a real (but unseen) segment of mantle has been invested with some of the attributes of an arbitrary geochemical standard. This can lead to bewildering mixtures of hypotheses and observations, but without making any assumptions about the previous history of the mantle, it is still possible to deduce from the chemistry of lavas that their sources were different at the time of melting. More and more geochemists have favoured heterogeneity in the mantle to account for the differences between fresh lavas of similar major element chemistry, when these have been erupted contemporaneously in the same region¹⁷. In favourable circumstances it may be possible to conclude in favour of heterogeneity even on the basis of major element ratios in lavas, for example, Mg/Fe (ref. 24), but most cases are based on the range of incompatible elements depicted in Fig. 1.

If chemical heterogeneity in the oceanic mantle is accepted, the debate can turn about the nature and extent of the variations, and their cause and timing. Often the most that can be deduced from lava chemistry is that the sources were richer or poorer in particular elements by comparison among the samples, or against some chosen standard. By adding isotope systematics, it can be argued that the observed lava isotope patterns cannot be explained by undisturbed isotopic evolution in the source throughout the entire history of the Earth (Fig. 2). This proposition is made more plausible by the difficulty in conceiving of a segment of mantle that could have remained totally isolated for 4,600 Myr, but note that the isotope systematics are based on meteorite abundances and must rest on assumptions about isotopic distributions in the primordial Earth. If it is accepted that the systematics define the expected behaviour in a closed system within the Earth, the departures from the geochron indicate that the isotopic development of a particular piece of mantle has been disturbed. Depletion then usually means Rb deficiency, and is almost always ascribed to earlier episodes of melt extraction from primordial, primitive, or fertile mantle. Similar deductions have been made for Nd/Sm (ref. 27), Th/Pb, U/Pb and Pb isotope distributions: diagrams similar in principle to Fig. 2 may also be constructed, but Nd/Sm data are less abundant, and the complexities of the Pb systems require more extensive coverage for satisfactory presentation²² Taken in concert the isotope patterns in a lava can make an impressive case for a complex history of its mantle source²⁵

Enrichment (such as Rb excess) implies source mixing, the simplest interpretation being that two sources have been mixed, but the nature of the mixing, the number of mixes, and the real number of sources, are matters of conjecture. It might be that melts from deeper sources have become lodged in and contaminated higher mantle levels, which are then subsequently remelted 12.28-31 or a variety of melts have mingled in their passage to the surface, maybe as a complex continuum. Alternatively, fluids from another mantle source have contaminated melts at higher levels 2 or metasomatized the mantle through which they pass 3. The lava erupted at the surface may be the product of any combination of such processes, or others as yet unknown. But all that the 'disturbed' isotope patterns in lavas reveal is that the mantle sources have not had a simple history. Careful integration of different chemical evidence, such as

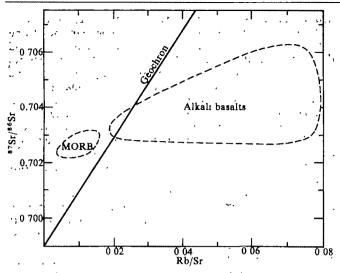

Fig. 2 Rb-Sr isochron diagram showing fields of alkali basalts and MORB. The 4,600 Myr isochron (geochron) indicates the distribution that would be expected from isolated (closed) mantle domains that had the same primordial ⁸⁷Sr/⁸⁶Sr as basaltic achondrite meteorites (BABI), but different Rb/Sr when the Earth was formed. Compositions left of the line have Rb insufficient for, and those to the right Rb in excess of, the amount necessary to support their observed ⁸⁷Sr, if the geochron prescription is correct. The simplest explanation is that the Rb-Sr systems in the mantle sources have not remained undisturbed, suggesting loss of Rb from the MORB sources and gain by the island volcano sources. From refs. 12, 26.

combined isotopes, trace elements and element ratios, can be developed into a forceful argument for source enrichment before melting³⁰. With improved geochemical understanding, and more information, it may be possible to discriminate in favour of enrichment by volatile activity, and metasomatism may then be the most plausible process; but the ultimate proof of metasomatism can be imprinted only in the mantle solids.

Volcanological evidence

Mafic and ultramafic lavas form the bulk of the material for geochemical conclusions in favour of mantle metasomatism, and it is therefore ironic that often the geology or volcanology of the specimens is accorded little or no weight in the argument. Those igneous rocks with the highest contents of incompatible elements have long been referred to by petrologists as 'alkaline', so that abundance of K and Rb, two of the prime incompatible elements in modern discussions, is already implicit. Alkaline magmatism, oceanic and continental, is characteristically expressed in central volcanoes and igneous complexes, giving rise to fragmental, explosive and sometimes high velocity eruptions³⁴. It is these last that carry up ultramafic fragments (nodules), providing solid samples of the deepest available mantle. Furthermore, fast eruption allows little opportunity for modification of the melt as it rises to the surface, and provides some of the best samples of mantle melting. Other incompatible elements are thus manifest in alkaline igneous activity, namely the gases which are the cause and driving force of high speed eruption. Furthermore, the gases in this magmatism are distinctive, especially in their contents of CO₂, Cl and F (refs 34-36). Therefore richness in alkalis (and other incompatible elements) and gases is no coincidence8, and was a prime reason for proposing mantle metasomatism as an essential part of alkaline igneous activity9. This does not say that the volcanological evidence is anything other than circumstantial (as indeed is the geochemistry of lava samples), simply that in considering the case for mantle metasomatism all the evidence should be weighed:

Against this volcanological background, the petrographical evidence of metasomatism in mantle nodules brought to the surface by igneous eruptions should be viewed.

Petrographical evidence

To know that metasomatism has happened, the evidence must be seen in the rock, and solid samples of mantle are available only as volcanic xenoliths, and peridotite masses in fold mountain belts. The latter may have been emplaced as relatively cool tectonic slices, or hot intrusions, forced through the Earth's crust. Some contain veins of less refractory minerals, and veined peridotite has been held up as one exemplar of 'enriched' mantle that might yield alkali basalts by preferential melting of the vein material 30,37,38. The veins have been interpreted as formed by melt injection, or segregation. Evidence of metasomatism while the peridotite was still in the mantle is not yet available, and may not be easy to distinguish from low-pressure changes after emplacement in the crust. Hence the only petrographical evidence of metasomatism is in mantle nodules of volcanic derivation. Even here careful observation is necessary to eliminate the possibility that the changes did not result from reactions between a peridotite fragment and the high temperature, volatile-rich melt which brought it to the surface.

Peridotite nodules consist dominantly of olivine and orthopyroxene with, or without, small amounts of clinopyroxene, and/or spinel, and garnet. It is these last three minerals especially that contain the Ca, Al and Na, and are consequently important contributors to basaltic liquids, the most common surface products of mantle melting. Spinel peridotites are typically carried up in alkali basalt (basanite) eruptions, while garnet-bearing varieties are much more restricted, and largely confined to strongly silica-unsaturated volcanics, such as melilitites, and especially kimberlites. All these nodule carriers are notably rich in incompatible elements, but even tholeiitic basalts have K and H₂O contents that are hard to account for by realistic degrees of melting of peridotite unless it contains small amounts of an additional phase, such as amphibole³⁹ or phlogopite mica⁴⁰. Experimental studies⁴⁰⁻⁴³ indicated that these minerals had appropriate stabilities for existence in the upper mantle, but early reports of amphiboleand mica in peridotite nodules were circumspect, either because the minerals seemed secondary (and formed outside mantle conditions)44 or because the peridotite nodules might be magmatic crystal accumulations (and not accidental inclusions picked up by the magma)⁴⁵. But evidence was mounting in favour of most peridotite nodules being mantle samples and textural studies soon left little doubt that in some peridotites, phlogopite⁴⁸ and amphibole⁴⁹ had grown in equilibrium. These hydrous minerals were seen as either an integral part of the mineralogy of the mantle sampled by the eruption 48,49, or formed as a result of igneous veining around a magma body in the mantle⁵⁰. In one case it was suggested that direct melting of amphibole peridotite could have produced the nephelinite melt that brought the fragments to the surface⁴⁹.

Mica and amphibole are the two most characteristic metasomatic minerals in peridotite nodules, the process being recognized by intricate partial replacement of the earlier minerals. New minerals invade the old in delicate lobes and embayments, until the stage may be reached where only scattered (but undisturbed) residuals remain: the rock is pervaded by infiltration ('seepage') of new material along grain boundaries, and even along cleavage planes in the existing minerals¹¹. Clinopyroxene also forms metasomatically, its composition being distinctly different from any that may be present in the original peridotite^{51,52}. A suite of samples can show all stages from incipient metasomatism of peridotite through to complete transformation into mica-amphibole-clinopyroxenite. This latter rock has been found containing residuals of peridotite still intact¹¹: The minerals most susceptible to replacement are garnet, spinel and orthopyroxene, followed by olivine. Other new minerals introduced are carbonates, phosphate (apatite), and titanium and iron oxides and sulphides 11,53,54. By its very nature, metasomatism must yield varied end products, but the process may add K, Ti, Al, Fe, Mn, Ca, Na, H, C, S, P, Rb, Sr, Y, Zr, Nb, Ba and La (ref. 11), in different amounts. This is an impressive

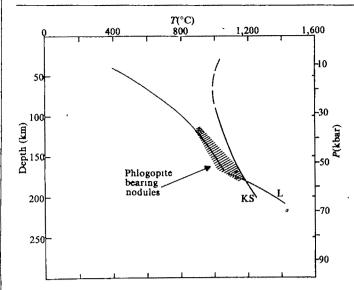

Fig. 3 Distribution of phlogopite-bearing mantle nodules from Lesotho kimberlites in relation to the geothermal gradient (L), and kimberlite beginning-of-melting (KS). Phlogopite has formed well outside the conditions where any melt can exist, and cannot be attributed to the action of magma. On the contrary, the melting curve may be the upper boundary for phlogopite survival in retrieved mantle samples. The distribution also suggests a maximum depth of ~200 km for metasomatized samples. Adapted from ref. 58.

array of incompatible elements, and the concentrations may also be remarkable: one opaque phase has been reported with 9.1% BaO and 7.4% ZrO₂. In addition to the pervasive alteration within the body of the rock, metasomatized peridotites are commonly cut by veins 11.53.54 containing assemblages of metasomatic minerals. These veins are truncated against lava at nodule margins, indicating that the nodules are fragments of larger masses disintegrated by eruption. In some cases there are small amounts of glass in the veins, with every sign that the liquid was in equilibrium with the vein minerals. This liquid, indicating the melting threshold, is in stark contrast with the host lava which corrodes and devolatilizes the hydrous minerals to clinopyroxene+olivine (±spinel)+glass 11.55. Furthermore, there are chemical gradients perpendicular to the veins within the nodules but not against the nodule margins 56. Thus, a range of observations rule out metasomatism of the nodules by the carrier melt at low pressure.

Not uncommonly the mica and amphibole in peridotite nodules is deformed^{54,57} in keeping with a time lag between its formation and nodule eruption. Furthermore, comparing mica bearing nodules with the mantle solidus on a PT diagram⁵⁸ (Fig. 3) shows that they equilibrated in conditions where no liquid could exist. Isotopic analyses of Sr in the metasomatic minerals and host nodules prove them to be out of equilibrium with the enclosing kimberlite, and indicate a significantly earlier metasomatic age⁵⁹. In other examples, although the metasomatized nodules and the recently erupted host lavas are in an isotopic harmony, the isotopic evidence requires the melts to be fusion products of mantle that had been metasomatized in an earlier event⁶⁰. Other studies reveal complex histories of changing chemical heterogeneity in the continental mantle, some of which were metasomatic, dating back to 3,000 Myr (refs 61, 62).

Conditions of metasomatism

Considerations of mechanisms (infiltration and diffusion) and the characteristics of the metasomatizing agents, are still in their infancy. Studies of the gaseous components of metasomatic amphiboles and micas indicate that the aqueous fluids coexisting with those amphiboles and micas brought up by alkali basalts were diluted by CO₂, O, F and Cl, while in samples from kimberlites all the H₂O may have been fractionated into

hydrous minerals⁵⁶. Experimental studies have already shown that fluids in equilibrium with synthetic phlogopite and olivine must contain considerable dissolved K, Al, and Si (ref. 3), and the agent of mantle metasomatism (whatever its precise nature) was clearly bringing in these and other large ion lithophile elements from greater depth. The ultimate, deep mantle source of the fluids is inaccessible, but the emission of gases from volcanoes is evidence of continual Earth degassing, and the key role of CO₂ in alkaline magmatism is of long standing³. Repetition of alkaline igneous activity in continental cratons predicates a persistent, or renewable, source of volatiles in the mantle^{34,36}. The same volatiles must be essential ingredients of the metasomatic process.

Figure 4 shows some experimentally determined mineral stabilities, and indicates that the most abundant metasomatic minerals in ultramafic nodules could have been formed by fluids moving through the mantle along typical geothermal gradients. Figure 3 shows this to be borne out by the metasomatized nodules in kimberlite pipes, and also indicates the expected upper boundary of the process—the onset of melting where the local geothermal gradients intersect the vapour-saturated solidus in the mantle. On low geothermal gradients, and with slow release of fluids from the deep mantle, metasomatism will continue and presumably affect a wider region, over a long period of time. But given a sufficient supply of fluid the channelways will become saturated with metasomatic minerals, and their temperatures will be raised, so that ultimately melting and the generation of alkaline magmas may be expected⁸. Such a regime explains the broad range of nodule types showing all degrees of metasomatism, and with some showing signs of melt formation. Upward leakage of volatiles can thus provide the means of chemical enrichment, and the trigger for igneous activity^{8,58}. A mechanism for volatile release and channeling through the lithosphere is shown in Fig. 5.

Volume relations

In fine detail the metasomatism in ultramafic nodules is nondisruptive, with undisturbed residual patches of the original host. At this scale part of the replacement may be equal-volume,

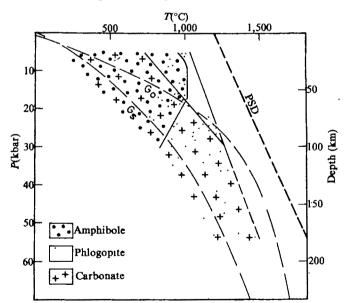

Fig. 4 Experimentally determined stabilities for possible metasomatic minerals, the boundaries (solid lines) indicating upper limits. Overlap of the stability fields cannot be used to infer necessary coexistence of minerals, which depends on factors such as bulk mantle chemistry, presence or absence of vapour (fluid), and fluid composition. Extensive mantle stability regions are indicated for continents (geotherm $G_{\mathfrak{g}}$) where alkali rich and carbonate magmatism are strongly developed. Mineral stability ranges, are much more restricted along typical oceanic gradients (G_0). PSD (heavy broken line) is the vapour absent peridotite solidus. Adapted from ref. 63. Experimental sources, refs 40, 43, 64, 65.

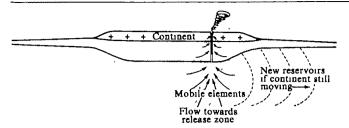

Fig. 5 Opening of a zone of weakness in the lithosphere allows volatile release to the surface. The escape channel effectively acts as a volatile and heat focus, leading to metasomatism and melting along the pathways. Adapted from ref. 34.

but it is almost impossible to rule out the possibility of rock distension along grain boundaries. Complete equal-volume metasomatism would require totally free exchange between the rock and the transporting medium, so that part of the original composition can be removed, as suggested in nodules from the Bultfontein kimberlite⁵⁴. In mantle conditions the bulk of any fluid entering a region where metasomatic minerals were stable would be consumed in carbonation and hydration reactions. Expansion is then unavoidable, making fluid escape zones selfextending by what amounts to metasomatic wedging. Consistent with this is the common observation of veining in metasomatized nodules. Once a crack system is open in the host rock. chemical exchange between fluid and solid must become easier, evidenced by the new minerals being relatively homogeneous. Complex zoning and other heterogeneities are common, however, in metasomatic minerals, indicating a spectrum of replacement conditions. Metasomatic veining itself requires some opening up of the host rock, even though most of the minerals along the veins may have formed by replacement. A parallel exists in alkaline metasomatism (fenitization) around alkaline complexes in the crust, where the outstanding physical characteristic is extensive shattering and veining of the host rock, often with little sign of deformation, or even block rotation. Mantle metasomatism requires that a pre-existing volume of dense peridotite has been changed to one that is larger and less dense, which explains the remarkable correlation of alkaline magmatism with uplift of the cratons (coupled with geophysical evidence of a lower density mantle)^{9,11}. Uplift by this process has the advantage of long survival, in contrast to uplifts of purely thermal origin. In fact the metasomatic uplift can be removed only by surface erosion or by subsequent thermal decomposition in the mantle: the latter may explain part of the subsidence observed in continental rifts when the axial igneous activity becomes established36.

Is metasomatism widespread or local?

First descriptions of metasomatized peridotites indicated two different modes for the process. On one hand the metasomatized nodules formed only a fraction of the total mantle sample in a kimberlite vent, and were attributed to local metasomatism by magma before eruption⁵³. At the other extreme, throughout two whole volcanic provinces large proportions of the ultramafic nodules were metasomites, sometimes to the exclusion of unaltered peridotites¹¹. Substantial parts of the sampled mantle in south-west Uganda and west Eifel (Germany) consist of alkali clinopyroxenite, and in the Uganda samples garnet and orthopyroxene are absent, and olivine not abundant. The lavas in these (and like) provinces have always been burdened by a plethora of names, giving little or no indication of their mineralogical affinities and obscuring the fact that in essence they are fine-grained clinopyroxenites. Their chemistry is appropriate to their being partial melts from alkali clinopyroxenite mantle: K-rich lavas in Uganda where the nodules are rich in mica, and sodi-potassic lavas in the Eifel where amphibole is more abundant in the nodules^{11,66}. A parallel case can be made for kimberlite, which in its earliest description was called mica peridotite. Nodule suites in which large proportions of the samples contain amphibole and mica are not uncommon, and there seems to

be a spectrum of conditions from extensively metasomatized mantle to a patchy or network distribution. Where metasomatism is extensive (and intensive) the lavas look like daughter products, and there is growing support for the view that metasomatism is the precursor of alkaline magmatism ^{34,60,67}.

Even a volcanic province such as south-west Uganda, however, is only a tiny mantle sample, and the need now is to see metasomatism in the context of the mantle as a whole. Clearly material is being introduced into the upper mantle from below, but is it only a local effect⁶⁸⁻⁷¹ and therefore of relatively small significance in mantle processes, or is it more widespread^{9,11,61}? Work on nodules from different kimberlites and of different ages across the southern African craton has demonstrated the use of coordinating different lines of enquiry⁶¹. Mineral textures show metasomatic replacement in nodules from many kimberlites, and a detailed Sr isotopic study of nodules from one kimberlite suggests they have a distinctly greater age than that of the host kimberlite (90 Myr), the metasomatic event being tentatively related to the Karroo magmatism (190 Myr) that affected wide areas of Africa and the rest of Gondwanaland^{59,72}. Metasomatism in nodules from the Precambrian Premier kimberlite indicates an earlier manifestation of the process in the same region⁷³. New Nd isotope studies are indicating two different episodes of metasomatism in nodules from the same kimberlite (Bultfontein) (A. J. Erlank, personal communication). More and more kimberlite pipes are being discovered in southern Africa⁶⁸, and although the volume of kimberlite in each case is tiny, the southern African craton has clearly been peppered with kimberlite eruptions, providing widespread sampling of the underlying mantle. Proportions of metasomatized nodules vary^{53,54} so the metasomatism is patchy in mantle sampled by kimberlite; but the time relations, and the spatial distribution, require that the process, although variable in intensity, is general below the southern African craton. Similar patterns emerge elsewhere, and the world-wide occurrence of kimberlite and alkaline magmatism bringing up mantle xenoliths containing amphibole, mica, and apatite suggests that metasomatism of the mantle, especially the subcontinental mantle, is widespread. The multiplicity of alkaline magmatism across the continents throughout their history indicates that metasomatism is not just an anomalous feature in an otherwise barren mantle. The age ranges, from Precambrian through to present, indicate a continual process, and the persistent association of metasomatized nodules with alkaline magmatism must surely mean that the metasomatizing fluids and the magmatism repeatedly exploit, as channels, long-lived weaknesses in the lithospheric plates⁷⁴.

Wider considerations

Geochemistry, and observational and experimental petrology show that the mantle is heterogeneous. Much of the Earth's thermal activity is expressed in submarine eruption at midocean ridges, and this has lent credence to the view that the continental upper mantle is largely depleted in its low melting constituents, and is barren, infertile, or effectively dead. Active volcanoes in continental interiors indicate a counter view, but their relative paucity perhaps causes them to be set aside as anomalies⁷⁵, or the progeny of mythical plumes. It is easy to overlook the fact that the cratons are the oldest parts of the Earth's surface, and since they became stable they have been repeatedly perforated, across their breadth, by alkaline igneous activity. Even tholeiitic flood lavas erupted on a regional scale may show significantly higher levels of incompatible elements than could be expected from a highly refractory residual mantle⁶¹, and some have chemical features close to that of the postulated bulk Earth 75 . The magmatism is a constant reminder that development of the continental mantle is far from complete. Repeated and widespread metasomatism of the mantle lithosphere would account for this activity, and would also be expected to contribute to continental growth by additions to the base of the crust^o. Continental permanence and constancy of crustal thickness could be maintained in the face of the fact that erosion now exposes Archaean deep crust at the surface. If the continental mantle is not exhausted, it raises the possibility that the special characteristics of the ancient cratons are inherited from original accretionary inhomogeneities in the formation of the Earth³⁴. Undoubtedly, the continental lithosphere still has challenges that can engage the scientific collaboration envisaged in the International Lithosphere Programme.

Resolving crystallographically distinct tetrahedral sites in silicalite and ZSM-5 by solid-state NMR

C. A. Fyfe^{††}, G. C. Gobbi[†], J. Klinowski[‡], J. M. Thomas^{††} & S. Ramdas[‡]

† Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Ontario, Canada N1G 2W1 ‡ Department of Physical Chemistry, University of Cambridge, Lensfield Road, Cambridge CB2 1EP, UK

'Magic-angle-spinning' NMR has revealed fresh insights into the atomic structure of the polymorph of silica, silicalite, which has exceptional absorptive properties. There is evidence that highly crystalline variants of silicalite contain 24 distinct tetrahedral locations, populated principally by Si⁴⁺ ions, and that, contrary to what was originally thought, aluminium is also present, in at least two kinds of environments, in the tetrahedral framework. The silicalite structure is shown to be essentially indistinguishable from that of the siliceous zeolite catalyst ZSM-5.

THE new, thermally stable, crystalline phase of silica called silicalite described by Flanigen et al.1, possesses remarkable sorptive properties that stem partly from its exceptionally large internal volume (33% porosity) and partly from its three-

dimensional system of intersecting channels¹. It contains fivemembered rings in basic repeats (Fig. 1a) which are so arranged as to form a system of channels made up of 10-membered ring openings (Fig. 1b). Silicalite is hydrophobic, and it removes from water, by preferential adsorption, alkanols, certain alkanes and some other organic entities. It has been argued that

^{*} To whom correspondence should be addressed.

"... unlike aluminium-containing zeolites, silicalite has no cation-exchange properties . . . silicalite has no aluminium and no cations in its structure". The original patent² asserts that such aluminium as may be adventitiously present is in the form of Al₂O₃. Although the details of its crystal structure remain to be fully clarified, it is established^{1,3-5} that, topologically, silicalite is closely similar if not identical to the shape-selective catalyst-ZSM-5, which because it selectively converts methanol to petrol, is a key component in the production of fuel from coal $(C+H_2O(steam) \rightarrow CO+H_2; CO+2H_2 \rightarrow CH_3OH)$. There have been claims4 that silicalite is an end member of the ZSM-5 substitutional series, which embraces Si/Al ratios from 10 to 4,000. But because it is extremely difficult, if not impossible⁵, to ascertain by X-ray crystallography whether aluminium in very low concentration is present substitutionally in the cornersharing tetrahedral (SiO₄) array that constitutes ZSM-5 and silicalite, there is still considerable debate as to the distinction between these two materials. We now show, by magic-angle spinning⁶ NMR, that: (1) several crystallographically distinct sites for Si atoms in the lattice may be directly detected by ²⁹Si NMR; (2) the aluminium in silicalite is readily detectable by ²⁷Al NMR; (3) the Si/Al ratio may be straightforwardly estimated; (4) all the aluminium is tetrahedrally coordinated to oxygens; (5) there are at least two distinct types of tetrahedral site occupied by the aluminium. We further show that there are 24 distinct crystallographic tetrahedral sites occupied by either silicon or aluminium in silicalite/ZSM-5, and that its

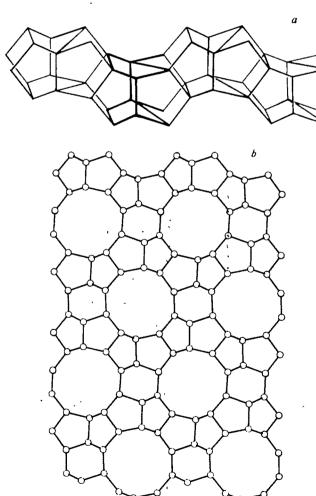

Fig. 1 The structure of silicalite. a, Secondary building units (indicated by bold lines) each composed of 12 Si atoms are linked into chains, one of which is shown in the c direction. b, The chains are interlinked to form a three-dimensional framework in which there are 10-membered ring openings (\sim 5.5 Å diameter) running along the [010] direction. In this portion of the ac structural projection, \bigcirc denotes a tetrahedral site.

space group has lower symmetry than the currently accepted Pnma³. We conclude that, structurally, silicalite and ZSM-5 are essentially indistinguishable.

Structure determination

High-resolution solid-state 29 Si NMR with magic-angle spinning (MASNMR) is capable of distinguishing between the five possible Si(nAl) structural building blocks in zeolitic aluminosilicates, where n=0 to 4 is the number of tetrahedral Al atoms joined, by oxygen bridges, to the central Si atom⁷⁻¹⁰. In the spectra of crystalline synthetic faujasites (zeolites X and Y) for example there are up to five well-resolved signals falling within distinct chemical shift ranges; thus the value of n can be assigned to each signal, aiding structural elucidation¹¹⁻¹³.

By using ²⁹Si MASNMR at very high magnetic field¹⁴ on a sample of silicalite of very high purity and crystallinity prepared exactly as given in example 4 of ref. 2 but afterwards calcined in air at 500 °C for 16 h, we have obtained spectra of such high resolution that we can resolve separate ²⁹Si signals attributable to several crystallographically non-equivalent tetrahedral Si atoms, all joined, by oxygen bridges (denoted by straight lines in Fig. 1a, b), to four other Si atoms. These spectra, together with the corresponding ²⁷Al MASNMR spectra, provide new insights into the structure of silicalite.

Results

Figure 2 shows the 29 Si spectrum recorded at 79.80 MHz without using any resolution-enhancement techniques. The sharpness of the spectrum is exceptional, with FWHM of the resolved peaks of \sim 40 Hz (\sim 0.5 p.p.m.) which is superior to that so far observed in any other zeolite, even at this very high magnetic field. The complete spread of all the components of the spectrum (chemical shifts are given from external Me₄Si) is \sim 6 p.p.m. The chemical shift range of all the peaks (-112 ± 3 p.p.m.) is characteristic of Si(0A1) (that is Si(4Si)) groupings

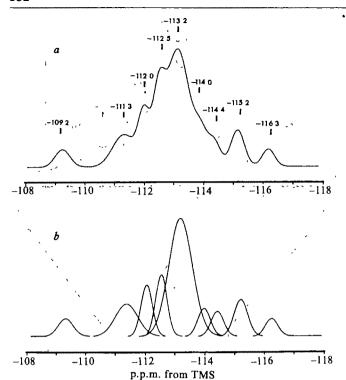

Fig. 3 The ²⁹Si MASNMR spectrum given in Fig. 2 can be computer-simulated using nine gaussian-shaped peaks, shown individually in b; their sum, simulating the spectrum, is given in a. The areas of the peaks in b are, from left to right, in the ratio 0.98: 2.70:2.19:2.63:10.35:1.30:1.16:1.87:0.82.

37 1. 2 2

in highly siliceous materials 7-10. The observed multiplicity arises from the crystallographically non-equivalent tetrahedral environments of Si(4 Si) silicons. The spectrum may be simulated by a minimum of nine gaussian signals, the intensities (peak areas) of which are approximately in the ratio 1:3:2:3:10:1:1:2:1 (see Fig. 3). Using the intensities of the well-resolved lowest and highest field signals as a base unit of one (that is we proceed on the plausible assumption that these well-resolved peaks each refer to one distinct tetrahedral site), the total intensity of the peaks in the Si(4 Si) multiplet is found to be approximately 24. This result suggests a space group which requires 24-non equivalent Si sites in the repeat unit of the structure. It signifies that Pn2₁a or P2₁/n (see below) are more appropriate than Pnma³ which has only 12 distinct tetrahedral sites. The relative intensities of the signals do not suffer perceptible change over a 10-fold increase in the delay time of the experiment, thereby indicating that they are quantitatively reliable. At this stage, it is premature to attempt to assign individual 29Si peaks to specific sites, particularly because

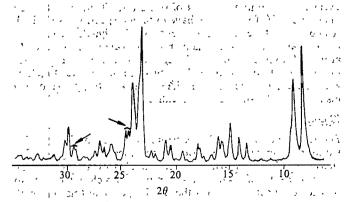

Fig. 4 Powder diffraction pattern of silicalite obtained on a Philips vertical goniometer using Cu K α radiation selected by a curved graphite monochromator in the diffracted beam. Peak doublets are arrowed.

interatomic distances in silicalite are not sufficiently well established (see footnote 11 of ref. 5).

Figure 4 shows a powder X-ray diffraction pattern of silicalite (the same sample as used in the MASNMR measurements shown in Fig. 2). Note the presence of peak doublets (marked with arrows) for 2θ values of 24.4° and 29.2° . Pseudosymmetry is common in zeolite structures and monoclinic as well as orthorhombic symmetry has been observed in ZSM-5-type materials. Wu et-al. simulated peak splitting by the introduction of monoclinic lattice parameters a = 20.17 Å, b = 19.93 Å, c = 13.42 Å and $\alpha = 90.64^{\circ}$, instead of the orthorhombic values of 20.07 Å, 19.92 Å, 13.42 Å and 90° , respectively. This small change in the unit cell causes the symmetry

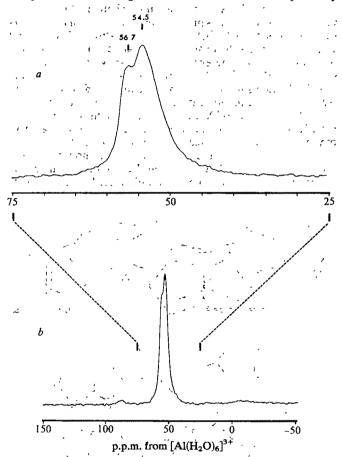

Fig. 5. High-resolution ²⁷Al MASNMR spectrum of silicalite at 104.22 MHz. 176,214 free induction decays were accumulated; repetition time 0.1 s. Chemical shifts are given in p.p.m. from [Al(H₂O)₆]³⁺. Note the absence of octahedrally coordinated aluminium in the sample.

elements such as the mirror planes parallel to (010) bisecting the zigzag-shaped channels to disappear; there are thus 24 (rather than 12) crystallographically non-equivalent Si atoms. The probable monoclinic space group for ZSM-5-type materials is, therefore, thought 15 to be P2₁/n. Change of symmetry occurs quite readily for ZSM-5 materials: indeed, a commercially available sample of silicalite exhibited an X-ray pattern identical to that shown in Fig. 4.

Discussion

The 27 Al MASNMR spectra show a rather broad absorption centred at ~ 55.6 p.p.m. with respect to external $[Al(H_2O)_6]^{3+}$, clearly characteristic of tetrahedral coordination 17 , both in this and in all other silicalite samples, which we have examined. In the sample the 29 Si spectrum of which is given in Fig. 2, the peak shows fine structure (Fig. 5) due to at least two components (at 54.5 and 56.7 p.p.m.) indicating the presence of crystallographically non-equivalent sites for tetrahedral aluminium. This agrees with the 29 Si spectrum in Fig. 2 and indicates that

the aluminium is tetrahedrally incorporated into the framework. Because of the 100% isotopic abundance of ²⁷Al and its very short spin-lattice relaxation time, even traces of aluminium are detectable by this sensitive technique. The aluminium in silicalite comes from impurities in the materials used in synthesis, and their level varies from sample to sample. The amount of Al present is small, but in all the samples of silicalite we have examined Al is tetrahedral and not present as occluded Al₂O₃ impurity² as the various forms of Al₂O₃ which we have investigated for comparison show an intense NMR peak at 9 ± 1 p.p.m. (reflecting octahedral coordination of Al) and in some also a small peak at 72±3 p.p.m. due to tetrahedrally coordinated17 Al, in agreement with structural data18 on yalumina. A quantitative determination by ²⁷Al MASNMR of Al concentration in the sample of silicalite was carried out by adding a known amount of a reference compound containing octahedrally coordinated Al and comparing the intensities of the two signals. This gives a Si/Al ratio ≥ 1,000. The aluminium content of the commercial silicalite sample was found to be higher (Si/Al \geq 200) and a small broad peak at -104 p.p.m. corresponding to Si(1Al) (that is Si(0Al) (0Si)₃ group) is clearly observed in the ²⁹Si MASNMR spectrum.

We have found general correspondence between the 29Si MASNMR spectra of silicalite on the one hand, and those for

a variety of ZSM-5 zeolite preparations on the other. The latter show in the ²⁹Si MASNMR spectra an intense peak at about -112 p.p.m. with some indications of fine structure and a much smaller peak at approximately -105 p.p.m. corresponding to Si(1Al); and in the ²⁷Al spectrum a single peak at ~55 p.p.m., identical to that found at essentially this position in silicalite. The ²⁹Si spectra of ZSM-5 zeolites can, to a first approximation, be simulated by applying a large line-broadening function to the silicalite spectrum of Fig. 2, thus confirming the close? structural relationship between the two materials.

This work demonstrates the power of MASNMR as a structural probe for a large class of shape-selective aluminosilicate sorbents and catalysts.

We acknowledge support from the Universities of Cambridge and Guelph and from BP Research Centre, Sunbury. C.A.F. acknowledges the financial support of the Natural Sciences and Engineering Research Council (NSERC) of Canada in the form of an operating grant, G.C.G. the award of a NSERC Graduate Scholarship. We thank Dr D. Stewart, Dr B. Nay and Dr M. Barlow for making available the special preparation of highly crystalline silicalite. The NMR spectra were obtained at the South-West Ontario High Field NMR Facility (Dr R. E. Lenkinski, manager) funded by a Major Installation grant from NSERC.

Monitoring of structural changes accompanying ultrastabilization of faujasitic zeolite catalysts

J. Klinowski*, J. M. Thomas*†, C. A. Fyfe†‡ & G. C. Gobbi‡

* Department of Physical Chemistry, University of Cambridge, Lensfield Road, Cambridge CB2 1EP, UK [‡] Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Ontario, Canada N1G 2W1

By recording high-resolution solid-state NMR spectra of zeolitic samples spun (at ~3 kHz) at the magic angle $(\theta = 54^{\circ}44')$ so that $3\cos^{2}\theta - 1 = 0$ to the magnetic field, the chemical identity of the first and second coordination shells surrounding Si may be determined, and a distinction made between octahedrally and tetrahedrally bonded Al. The technique, therefore, enables the atomic course of dealumination, known to be responsible for the stabilization of catalytic zeolites, to be directly determined.

SYNTHETIC analogues of the rare mineral faujasite (Fig. 1) can be prepared in mild laboratory conditions such that materials with a wide range of compositions (zeolites X and Y with Si/Al ratios from 1.18 to 2.75) may be produced^{1,2}. The topology and overall crystallography of the aluminosilicate framework remain constant, but the population of Si4+ and Al³⁺ ions in the tetrahedral sites depends on the Si/Al ratio. These zeolitic solids, which are capable of cation exchange, possess large internal areas ($\sim 800 \text{ m}^2 \text{ g}^{-1}$) and volumes ($\sim 50\%$ porosity) and attractive molecular sieving properties. The diameter of the connected intracrystalline cavities varies between ~7 and ~13 Å. It has long been recognized that faujasitic zeolites are good catalysts for the cracking of petroleum; but in their as-prepared condition they proved

inadequate for hydrocracking, mainly because of their excessive acidity. A major turning point in the use of synthetic faujasites in catalytic cracking and hydrocracking came with the demonstration^{3,4} that on heat-treating NH₄-exchanged zeolite Y ultrastable catalysts were produced. These materials can withstand temperatures of ~1,000 °C, retain their internal surface areas and exhibit desirable hydrocracking activity. Over 200,000 tons of ultrastable zeolites are now produced annually: faujasitic catalysts are the cornerstone of the petroleum industry.

It is known from chemical analysis, and indirectly from the reduction of the unit cell dimension (monitored by X rays) that the Si/Al ratio increases markedly, a fact which both improves the stability and quells the acidity. But what are the atomic rearrangements associated with the process of ultrastabilization? There has been much speculation: it has been surmised

[†] To whom correspondence should be addressed

that the dealumination gives rise to detrital aluminous entities. In what form is this produced; and which are the groupings in the parent zeolite that are demolished?

Magic-angle spinning NMR

²⁹Si and ²⁷Al magic-angle spinning NMR (MASNMR)⁵⁻¹², is well suited to answer these questions, because it provides direct information pertaining to the immediate local environment of two kinds of atoms. ²⁵Si MASNMR readily and quantitatively identifies the groupings Si(O-Al)_n(O-Si)_{4-n} where n = 4, 3, 2, 1 and 0; and ²⁷Al MASNMR easily distinguishes ^{13,14} between tetrahedrally and octahedrally bound Al³⁺ ions. (For brevity we write Si(nAl) for the grouping Si(O-Al)_n(O-Si)_{4-n}.)

It is proposed 15 that ultrastabilization proceeds as follows:

Thus the framework vacancies created by the removal of aluminium (accompanied by a decrease in ion-exchange capacity) are thought to be subsequently re-occupied by silicon ¹⁶ or aluminium ¹⁷. The interstitial aluminium can be removed by leaching with acid. Ultrastabilization is facilitated by the presence of water vapour. Materials with very high Si/Al ratios are prepared by repeated ammonium exchange, heat treatment and the removal of interstitial aluminium.

Despite detailed studies of stabilization using various techniques, its mechanism remains unclear, particularly concerning the origin of the silicon required for the proposed second stage. This may come from the surface or amorphous parts of the sample; or from extensive recrystallization. We shall demonstrate that a combination of ²⁹Si and ²⁷Al MASNMR provides new insights into the mechanism of ultrastabilization. In essence, by recording NMR spectra at the magic angle, extremely sharp resonance lines are obtained from solid samples, comparable in width with those normally obtained

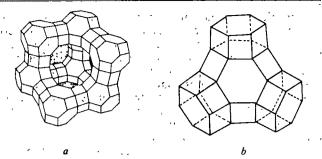

Fig. 1 Some features of the faujasite structure. a, The faujasite framework showing 14-hedral cages linked through six-membered rings, and supercages joined through circular windows. Tetrahedral atoms are located at the corners of polygons with oxygen atoms halfway between them. Non-framework cations are not shown. b, Tetrahedral linking of 14-hedral cages in faujasite. For clarity, the six-membered ring at the back of the cage is not shown.

from solutions or liquids. Chemical shifts are therefore measurable even in solids.

Experimental

²⁹Si MASNMR spectra were obtained at 79.80 MHz using a Bruker WH-400 narrow-bore spectrometer equipped with a magic-angle spinning attachment¹⁸ of the Andrew-Beams type¹⁹. Spinners, with an internal volume of ~450 μ l, were made of Delrin and spun at a rate of ~3 kHz. Cross-polarization and proton decoupling were not used. Intervals of 5 s were allowed between pulse sequences and 500–5,000 free induction decays were accumulated per sample. All ²⁹Si chemical shifts were measured from external tetramethylsilane, with high field shifts being negative. Experimental spectra have been computer simulated based on gaussian peak shapes, and the relative intensities of Si(nAl) signals calculated and corrected for the spinning sidebands. ²⁷Al MASNMR spectra were recorded at 104.22 MHz also using a home-made probe. ²⁷Al chemical shifts were recorded with respect to $[Al(H_2O)_6]^{3+}$ as an external reference; 3,000 free induction decays were accumulated per sample.

We have examined a series of four samples subjected to different types of treatment. Commercial zeolite Na-Y with Si/Al = 2.61, unit cell composition Na₅₃Al₅₃Si₁₃₉O₃₈₄·240 H₂O (established by X-ray fluorescence) and the (cubic) cell parameter a = 24.70 Å was the starting material. It was 75% exchanged with ammonium sulphate solution yielding NH₄-Na-Y zeolite (sample 1). Figure 2a shows the ²⁹Si MASNMR spectrum of this material; as expected, it is identical to that for the original Na-Y (not shown). Because in synthetic faujasites the first-order neighbourhood of every Al atom is Al(4Si), that is the Loewenstein rule strictly applies^{6,11}, the Si/Al ratio of the tetrahedral anionic framework can be calculated^{11,12} from the signal intensities I_{Si(nAl)} as

$$(\text{Si/Al})_{\text{NMR}} = \frac{\sum_{n=0}^{4} I_{\text{Si(nAl)}}}{\sum_{n=0}^{4} 0.25 n I_{\text{Si(nAl)}}}$$

thus providing a quantitative method of measuring zeolitic composition independently of elemental chemical analysis. Gaussian deconvolution of the ²⁹Si spectrum of sample 1 (Fig. 2a) leads to the ratio of intensities of the four peaks of 12.3:36.6:43.8:7.3, corresponding to (Si/Al)_{NMR} = 2.60, in excellent agreement with the value for the original Na-Y (by XRF and by NMR).

We note that when Si/Al ratios determined for synthetic faujasites by ²⁹Si MASNMR do not coincide with those obtained by chemical methods, it means that non-framework Al or Si: (such as detrital silica or adventitiously bound aluminous species) are present. This is clearly not the case in sample 1, the ²⁷Al spectrum of which is given in Fig. 3a. The single, relatively narrow signal with a chemical shift of 61.8 p.p.m.

and

ion

(sample 4).

d.

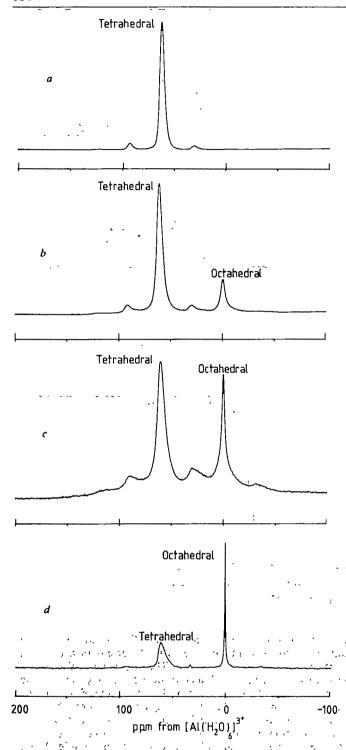

corresponds to the tetrahedrally bound aluminium (the small humps on the baseline, equidistant from the peak are spinning sidebands arising from chemical shift anisotropy).

Sample 2 was prepared by calcining sample 1 in air for 1 h at 400 °C. Its ²⁹Si spectrum (Fig. 2b) is significantly different from that for sample 1, showing a considerable decrease in the intensity of Si(3Al) and Si(2Al) signals with respect to Si(0Al). The calculated intensity ratio is now 4.8:24.6:55.3:15.3, leading to Si/Al ratio of 3.37 in the framework. Chemical analysis shows, however, no change in composition; clearly MASNMR is a superior analytical tool for the study of the status and quantity of chemical elements in the solid state. The observed increase in Si/Al ratio signifies that 23.3% of aluminium has been removed from the framework, with a corresponding loss of ion-exchange capacity. The ²⁷Al spectrum (Fig. 3b) is also markedly changed, showing two distinct signals: a large one (at 61.0 p.p.m.) corresponding to aluminium still remaining in tetrahedral sites, and a smaller one (at 0.59 p.p.m.) corresponding unmistakably to Al in octahedral coordination. This aluminium is now in the interstitial cationic positions, the ratio, r, of the intensities of the tetrahedral and the octahedral signals being 5.44 (the curve-fitted peaks were found to be exactly lorentzian). The total amount of aluminium in sample 2 is the same as in sample 1, as no washing was involved. Simple calculation leads to the expression Si/Al = 2.61(r+1)/r = 3.09for the composition of the tetrahedral framework. This value

is lower than 3.37 calculated from the ²⁹Si spectrum, but the difference corresponds to only three Al atoms in a unit cell containing 192 tetrahedral atoms. The intensities of the signals in both the ²⁹Si and ²⁷Al spectra do not display appreciable change over a 10-fold increase in the delay time of the experiment, which indicates that they are quantitatively reliable.

Sample 3 was prepared by heating NH₄-Na-Y to 700 °C for 1 h in the presence of steam. The ²⁹Si spectrum (Fig. 2c) is completely transformed with respect to that for samples 1 and 2. The Si(3Al) peak has disappeared, and the intensity ratio of the Si(2Al), Si(1Al) and Si(0Al) signals is now 10.7:36.7:52.6, leading to the framework composition $(Si/Al)_{NMR} = 6.89$. The Al spectrum (Fig. 3c) shows considerable amounts of octahedrally coordinated aluminium, as evidenced by the resonance at 0.0 p.p.m. There is also some amorphous material responsible for the raised baseline; it is therefore difficult to calculate the ratio of intensities reliably. We estimate r = 1.62, giving Si/Al = 4.20, lower than the value obtained from the ²⁹Si spectrum. The interstitial Al could be only partly octahedral; indeed, by assuming that one-third of it is tetrahedral, in accordance with the reported spinel structure for γ -alumina^{11,20}, we obtain agreement between the framework Si/Al ratios calculated from ²⁹Si and ²⁷Al MASNMR, respectively. The same holds for the small difference observed for sample 2.

Sample 4 was prepared by repeated application of the procedure used for preparing sample 3, followed by prolonged

²⁷Al MASNMR spectra at 104.22 MHz. a, Sample 1. Small humps equidistant from the peak are spinning sidebands. b, Sample 2. c, Sample 3. d, Sample 4.

leaching with 1 M nitric acid. The product has very low aluminium content, with Si/Al>50 (by chemical analysis) and a unit cell parameter a = 24.31 Å. The ²⁹Si spectrum (Fig. 2d) shows one sharp peak (FWHM = 1.1 p.p.m.) at -106.9 p.p.m.. and a very small broad signal at ~-101.3 p.p.m., clearly attributable to some residual Si(1Al) units. The sample contains amorphous material (note the slight elevation of the baseline), but its bulk is evidently very crystalline, the conclusion supported by the very sharp X-ray diffractogram and IR spectrum. The ²⁹Si MASNMR spectrum strongly suggests that framework vacancies created by the removal of aluminium are subsequently re-occupied by silicon. If this were not the case, the spectrum would be more complex, reflecting a range of possible environments for Si atoms including one, two or three neighbouring hydroxyl groups. Cross-polarization, involving Si-O-H bonds, would prove illuminating here. We note that the chemical shift of the Si(4Si) signal in sample 4 is very close to that reported for quartz⁵ (-107.4 p.p.m.).

The ²⁷Al MASNMR spectrum of sample 4 (Fig. 3d) contains a broad (FWHM=7.1 p.p.m.) tetrahedral peak at 61.0 p.p.m. and an extremely sharp (FWHM = 0.8 p.p.m.) octahedral signal at 0.23 p.p.m. The latter, the sharpest ²⁷Al signal we have measured in any solid, is due to motionally free [Al(H₂O)₆]³ in the cationic positions, not removed by leaching with acid. The ratio of intensities of the two signals is ~3. Such octahedral aluminium that still remains, neutralizes the residual negative framework charge caused by the presence of tetrahedrally coordinated aluminium. If all [Al(H₂O)₆]³⁺ ions are exchangeable, an ion-exchange equilibrium is established during acid leaching between [Al(H₂O)₆]³⁺ and H₃O⁺ competing for the cationic sites. Such equilibrium generally favours multivalent cations. (Note that one octahedral Al atom balances the charge of three tetrahedral Al atoms,)

Discussion

A recent study involving sorption measurements of gases²¹ showed that materials prepared in a manner similar to that for sample 4 contain a secondary mesopore system with pore radii in the range 15-19 Å, suggesting that the silicon which reoccupies empty tetrahedral sites does not come exclusively from the surface or from amorphous parts of the crystals, but also from their bulk, probably involving the elimination of the entire sodalite cages. MASNMR seems to support this conclusion. The Si(4Si) peak in Fig. 2d, although sharp, is almost twice the width of the analogous peak that we measured^{9,10} in the highly siliceous faujasite prepared by treating zeolite Y with gaseous SiCl₄, and of very similar aluminium content. This suggests that the structure of the thermally dealuminated material is less perfect than that of faujasite dealuminated using SiCl4.

Construction of a functional human suppressor tRNA gene: an approach to gene therapy for β -thalassaemia

Gary F. Temple**, Andrée M. Dozy*, Kenneth L. Roy* & Yuet Wai Kan*

A human tRNA gene was converted to an amber suppressor by site-specific mutagenesis of the anticodon. The mutated $tRNA^{Lys}$ gene directed synthesis of a tRNA that suppressed the UAG amber nonsense mutation in β^0 thalassaemia mRNA. Such genes may be used to detect other nonsense mutations in mammalian cells and may provide an approach to gene therapy for β^0 thalassaemia due to nonsense mutations.

THE thalassaemias are a heterogeneous group of hereditary disorders characterized by defective globin chain synthesis1 They are broadly classified into two major subgroups, α and β thalassaemia, depending on whether α or β chain synthesis is impaired. Molecular studies reveal that many different kinds of mutations produce the thalassaemia phenotype. These lesions include structural gene deletions1, nucleotide substitutions in the intervening sequences that cause abnormal mRNA processing^{2,3}, and nonsense mutations in the coding region that lead to premature termination of globin chain production^{4,5}.

We previously characterized two different mutations that cause β^0 thalassaemia, a form of thalassaemia in which no β -globin chains are synthesized. In a Chinese patient, a AAG to UAG mutation converts the β^{17Lys} codon to an amber termination codon⁴, and in a Sardinian, a CAG to UAG mutation converts $\beta^{39\text{Gin}}$ to a terminator⁵. The latter mutation has been found in β^0 thalassaemia from other parts of Italy, Algeria and Morocco^{6,7}. The nonsense mutation in β^0 thalassaemia is suppressible in cell-free translation systems with a yeast ambersuppressor tRNA in vitro 5,8. If a functional suppressor tRNA gene were available, one could test its ability to overcome the nonsense mutation in β thalassaemia in vivo. We have now tested the feasibility of this approach by constructing a human suppressor tRNA gene and assessing its ability to suppress the nonsense mutation in β^0 thalassaemia in vivo in an oocyte

Transcription of human tRNA genes

A 1-kilobase fragment of human DNA that contains a tRNA Lys and a tRNA Gln gene has been isolated and completely sequenced (K. L. Roy, H. Cooke and R. Buckland, in preparation). The sequence of the tRNA^{Lys} gene is identical to the RNA sequence previously reported for rabbit tRNA^{Lys} (ref. 9). Neither gene contains intervening sequences. Based on their DNA sequences, tRNA transcribed from tRNA Lys and tRNA Gli should be 73 and 72 nucleotides long respectively, before the trinucleotide CCA is added to their 3' termini.

The sequence homology between the human tRNALys gene and the rabbit tRNA3 suggests, but does not prove, that the tRNALys gene is transcribed and the tRNA is functional. No information is available for the tRNA Gln gene. To test whether these two genes are transcribed in vivo, we injected them into the nuclei of Xenopus laevis, isolated the RNAs from the oocytes, and analysed the newly synthesized RNA on a polyacrylamide gel (Fig. 1a)^{10,11}. The major RNA products were 76 and 75 nucleotides long respectively, with some longer minor bands also visible. These findings suggested that the tRNA genes were transcribed and that the transcripts were processed.

‡ Present address: Bethesda Research Laboratories, Gaithersburg, Maryland, USA.

The lengths of the major tRNA bands indicated that CCA trinucleotides were added to the 3' termini of both genes. These bands were eluted from the gel, and their identities confirmed by fingerprinting (data not shown).

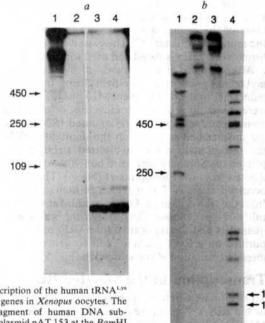

Fig. 1 Transcription of the human tRNA^{Lys} and tRNA^{Glo} genes in *Xenopus* oocytes. The 1-kilobase fragment of human DNA subcloned in the plasmid pAT 153 at the BamHI and HindIII site was cleaved with these two enzymes and EcoRI to produce the 220-bp and 800-bp fragments that contained the tRNA^{Gin} and tRNA^{Lys} genes respectively. Each fragment was subcloned in pBR322. An aliquot of 7 ng plasmid DNA (with either the tRNALys or tRNAGin gene insert), in a 25-nl solution that contained 10 mM HEPES (pH 7.9), 60 mM KCl, 0.3 μCi [α-32P]GTP (specific activity 450 mCi mmol⁻¹) was injected into the germinal vesicle of each oocyte 10,11. The oocytes were incubated at 19 °C in sterile modified Barth's solution (MBS-H) with 75 µg ml⁻¹ gentamycin and 40 µg ml⁻¹ bovine γ-globulin for 18 h. Each oocyte was

1 mg ml-1 Proteinase K, and incubated at 25 °C for 45 min. The RNA was twice extracted in phenol, precipitated in ethanol and electrophoresed on a 10% acrylamide gel containing 8 M urea¹². Autoradiography was performed for 3-18 h at -80 °C. Gel a, (1) DNA size markers (PM2 digested with HindIII); and RNA from oocytes injected with (2) pBR322, (3) and (4) pBR322 recombinants with the tRNAGIn and tRNALys genes respectively. Gel b, injection experiments similar to those shown in a performed with the RF of M13mp7 recombinants: (1) DNA size marker (PM2 digested with *Hin*dIII), (2) tRNA^{Lys} gene, (3) the mutated tRNA^{Lys} gene, (4) DNA size marker (M13mp7 digested with MspI).

then crushed and lysed in a 30-µl solution containing 100 mM Tris-HCl (pH 7.5), 300 mM NaCl, 10 mM EDTA, and

Mutation of the anticodon of the tRNA^{Lys} gene

We first mutated the anticodon region of the tRNA^{Lyn} gene to test its ability to function as an amber suppressor tRNA gene. The anti-sense strand of the tRNA^{Lyn} gene has the sequence AAA at the anticodon. To convert this gene so the tRNA will read the amber terminator UAG, we changed the AAA sequence to TAG using a synthetic pentadecamer (Bio Logicals) which was complementary to the anti-sense strand of the tRNA gene at the anticodon stem and loop, except for the two bases we intended to mutate. The sequences of the anticodon loop (anti-sense strand) of the tRNA gene and the primer used are shown in Fig. 2.

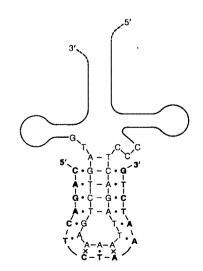

The strategy for mutagenesis is detailed in Fig. 3. The 800base pair (bp) DNA fragment that contained the tRNALy gene was subcloned into M13mp7 phage and single-stranded phage were isolated. The synthetic pentadecamer was used to prime synthesis of the complementary strand with DNA Polymerase I in the presence of T₄ DNA ligase in vitro, according to the method of Gillam and Smith^{17,18}. Initial synthesis was at 0 °C to maximize priming despite the mismatch; the temperature was then raised to 25 °C. The double-stranded closed circular forms were isolated on an agarose gel in the presence of ethidium bromide, and used to transfect Escherichia coli. Singlestranded phage were isolated from the culture and used as the template for a second round of synthesis which was carried out at 25 °C, without the initial 0 °C incubation, to favour hybridization of the primer with those phage that already contained the mutated sequence 18,19. The closed circular double-stranded forms were again isolated and used to transfect E. coli.

After a total of five rounds of synthesis, the success of mutagenesis was tested by hybridizing the ³²P-labelled pentadecamer to the recombinant M13 phage. Stringent conditions were used to allow hybridization of the primer to the homologous sequence in the mutated tRNA gene, but not to the mismatched sequence in the unmutated tRNA gene. All the recombinant phage hybridized strongly to the labelled primer on Southern analysis, but 90% of them had 300 bp deleted from the 800-bp insert (Fig. 4). The deletion probably occurred at an A-T rich region of human DNA downstream from the tRNA^{Lys} gene. One recombinant which contained the full 800-bp genomic DNA fragment was cultured in large quantities and the replicative form (RF) of DNA was isolated, purified on a CsCl gradient, and sequenced. It contained the intended mutation at the anticodon (Fig. 5).

Transcription of the mutated tRNA Lys gene

To determine whether the mutation affected the transcription of the tRNA^{Lys} gene, we injected the double-stranded RF of M13 DNA that contained the original and the mutated tRNA^{Lys} genes into the nuclei of *Xenopus* oocyte. Both produced

Fig. 2 Sequences of the anti-sense strand of the tRNA gene at the anticodon stem and loop, and the synthetic pentadecamer with the two-base pair mismatch (×) at the anticodon.

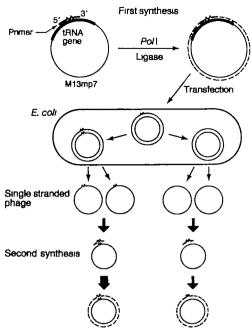

Fig. 3 Strategy of mutagenesis. The 800-bp DNA fragment that contained the tRNA^{L-n} gene with the BamHI and EcoRI ends was subcloned into the EcoRI site of the bacteriophage M13mp7¹³, after converting the BamHI site to an EcoRI site with linkers¹⁴. We selected the recombinant in which the anti-sense strand of the tRNA gene was contained in the single-stranded form of the M13 Single-stranded and RF forms of the recombinant phage were prepared 15.16. Site-specific mutagenesis with the pentadecamer was contained to Gullem and coworkers with modifications 17-19. A performed according to Gillam and coworkers with modifications¹⁷ 35-µl mixture that contained 2 pmol of the single-stranded M13 recombinant, 500 pmol of the synthetic pentadecamer, 100 mM NaCl, 40 mM Tris-HCl (pH 7.5), 20 mM MgCl₂, and 2 mM β -mercaptoethanol was heated to 70 °C for 10 min and then cooled slowly over 1 h to 0 °C. A 28- μ l aliquot was removed and the mixture adjusted to a final volume of 70 µl, which contained 29 mM Tris HCl (pH 7.5), 40 mM NaCl, 14 mM MgCl₂, 1.4 mM β mercaptoethanol, 500 mM each of 4 dNTPs, 240 mM ATP, 90 U mi⁻¹ Klenow fragment of DNA Polymerase I (New England Biolabs) and 100 U ml⁻¹ of T₄ DNA ligase (Bethesda Research Laboratories). The muxture was incubated at 0 °C for 30 mm and then at 25-27 °C for 4 h. The DNA was then electrophoresed on a 0.8% agarose gel in the presence of 2 μg ml⁻¹ ethidium bromide. The band that contained the closed circular double-stranded DNA was excised and eluted with glass beads²⁰. This DNA was used to transform E. coli, strain GM48 (Dcm⁻, Dam⁻), previously made competent with CaCl₂ treatment. 0.3 ml of transformed GM48 cells was mixed with 1 ml of JM103¹³ (at A_{660} of 0.2), and an aliquot was plated to determine the titre and prepare individual plaques for screening. The remainder was grown overnight at 37 °C and singlestranded DNA isolated from the supernatant to serve as template for repeated in vitro synthesis. In subsequent rounds of synthesis, the conditions were modified to favour priming of the mutated species by decreasing the primer-to-template ratio to 25 to 1 and omitting the mitial incubation at 0 °C^{17,18}. A total of five rounds of synthesis was performed.

approximately the same amount of 76-bp tRNA products expected for tRNA^{Lys} (Fig. 1b). Thus mutagenesis did not alter transcription of the tRNA^{Lys} gene.

Ability of the mutated tRNA^{Lys} gene to direct suppression of the amber codon

We then tested the ability of the mutated tRNA^{1.79} gene to produce a functional amber suppressor tRNA. We used the mRNA from a patient with β^0 thalassaemia due to a $\beta^{17Lyn(AAG)\rightarrow UAG}$ mutation. The β/α globin mRNA ratio in this patient's reticulocytes is 0.15 (ref. 4). We previously showed that suppression with a yeast serine-inserting amber suppressor tRNA in a cell-free system produces a β -globin chain with an altered chromatographic elution pattern because the β^{17Lyn} is replaced with serine⁸. If the mutated human tRNA^{1.78} gene produced a functional amber suppressor tRNA and inserted lysine at the β^{17} position, we would expect that a β -globin chain with a normal charge would be produced. Also, the length of the β -globin chain would not be affected, since the normal termination codon of β -globin mRNA is UAA²⁵.

Xenopus oocyte nuclei were first injected either with the normal or the mutated tRNA^{Lya} gene. The cytoplasm of the

oocytes was injected 20 hours later with polyA⁺ reticulocyte RNA from the β^0 -thalassaemia patient. The oocytes were incubated for another 48 hours in the presence of ³H-histidine and the protein was extracted. The globin chains were immunoprecipitated using a monoclonal antibody, eluted, and analysed on a Triton X-urea gel²⁶. As expected, no β -globin synthesis was detected in the oocytes injected only with the mRNA, or with mRNA plus the normal tRNA^{Lys} gene. However, in the oocytes injected with the mutated tRNA^{Lys} gene, the β^0 thalassaemia mRNA now directed synthesis of an authentic β -globin chain, as identified by immunological reactivity and electrophoretic mobility (Fig. 6). Hence the tRNA^{Lys} gene with the anticodon mutation functioned as an amber suppressor and most likely inserted Lys into the β^{17} position of the β -globin chain.

Discussion

We previously showed that in the two known types of β^0 thalassaemia due to nonsense mutations, the UAG codon can be suppressed in vitro by adding a yeast suppressor tRNA5.8. We undertook the present study to see whether this finding could provide an approach for in vivo gene therapy. To conduct in vivo DNA transformation experiments, we needed a suppressor tRNA gene. Although suppressor tRNA genes have been derived from bacteria and yeast, evidence suggests that some yeast tRNA genes are not processed correctly in mammalian cells (P. Berg, personal communication). Mammalian tRNA genes were therefore preferable for our experiment. Suppressor tRNAs have been identified in rabbit reticulocytes2 and bovine liver²⁸, but since no mammalian suppressor tRNA genes have yet been isolated, we constructed one in vitro. We mutated the anticodon of a tRNALys gene (AAA) to TAG (anti-sense strand) with a primer mismatched at the two-base sequence. We showed that this gene was transcribed and that the transcript functioned as an amber suppressor in vivo in Xenopus oocyte, because it read through the UAG codon in β^0 -thalassaemia mRNA. It is thus possible to convert a tRNA^{Lys} to an amber suppressor tRNA by mutating the anticodon.

The availability of mammalian suppressor tRNA genes offers a means of detecting nonsense mutations in higher organisms. At present, apart from viruses, bacteria and yeast, the only naturally occurring nonsense mutations known to cause diseases in higher organisms are the two defined in β -thalassaemia in humans⁴⁻⁶. Other nonsense mutations undoubtedly occur; just in the coding region of the β -globin gene there are 29 positions at which a single nucleotide substitution could produce a termination codon. Certain mouse and Chinese hamster cell lines with hypoxanthine guanine phosphoribosyl transferase

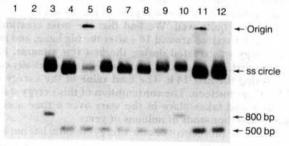

Fig. 4 Southern analysis of M13 recombinant phage. After the fifth round of synthesis, RF DNA from the cell pellet 16 was prepared from individual plaques, and the RF DNA from 35 of the mutated clones was digested with *Eco*RI, electrophoresed on an 0.8% agarose gel and transferred to nitrocellulose filters 22. The filters were prehybridized for 2 h, and then hybridized for 16 h with the synthetic pentadecamer, which was previously labelled with 32P at the 5' end, in a buffer containing 6×SSC, 10×Denhardt's solution at 41°C and 20 μg ml-1 yeast RNA. The filter was washed three times with 6×SSC for 20 min at 12°C23, dried and autoradiographed. *Lane 1*, DNA from M13; *lane 2*, M13 containing the unmutated tRNA¹⁻³⁷ gene; *lanes 3-12*, ten of the DNA samples containing the M13 tRNA¹⁻³⁷ gene after mutagenesis. All 35 clones isolated hybridized strongly to the probe. In all but two of the clones shown, deletions shortened the insert from 800 to 500 bp. The DNA from the clone shown in lane 10 was grown in large volume for further studies.

Fig. 5 Sequencing gel showing the mutated sequence in the anticodon region of the tRNA^{1,58} gene. The RF DNA prepared from the mutated clone shown in Fig. 4 was purified by CsCl banding for 48 h. A KpnI site, 55 bp from the anticodon was labelled with ³²P at the 3' terminus using T₄ DNA polymerase²⁴, and the sequence of the tRNA gene was determined by the method of Maxam and Gilbert on a 15% polyacrylamide gel in 8 M Urea¹².

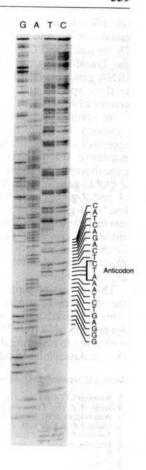

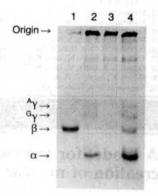

Fig. 6 Analysis of globin chain synthesis in Xenopus oocyte after injection with tRNA genes polyA+ mRNA from human reticulocytes and immunoprecipitation of globin with monoclonal antibodies. A sample of 7 ng DNA that contained either the normal or mutated tRNALys gene was injected into the nucleus of each Xenopus oocyte as described in Fig. 1, but without [α-32P]GTP. 20 h later, 10 ng of polyA+ reticulocyte RNA in 50 nl of 0.01 M Tris-HCI (pH 7.5), 0.02 M KCl, and 0.25 mM haemin injected into the cytoplasm at the equatorial band and incubation was continued at 19°C for 48 h after

adding 0.2 mCi ³H-histidine to each ml of the medium. Oocytes were washed twice in the incubation buffer, then squashed in a 5-µl solution per oocyte of 100 mM Tris-HCl (pH 6.8), 150 µg ml⁻¹ phenyl methyl sulphonyl fluoride (PMSF), and 2.5 mM EDTA. The lysate was clarified twice by centrifugation at 10,000 r.p.m. in an Eppendorf centrifuge. The extract from three oocytes was pooled and reacted with 25 µg of a monoclonal antibody against human globin in a 50 µl TENT buffer (25 mM Tris [pH 7.4], 10 mM EDTA, 350 mM NaCl, 0.15% Triton X-100, 1 mg ml⁻¹ bovine serum albumin). (This antibody reacts most strongly with human β -chains, but also reacts with α- and γ-globin chains.) After 18 h at 4 °C, 50 μl of a 10% suspension of Staphylococcus A in TENT buffer was added, and incubated at 4 °C for 6 h. The Stophylococcus A was pelleted by centrifugation at 10,000 r.p.m. for 2 min at 4 °C, and washed three times with the TENT buffer (without bovine serum albumin). Haemoglobin A 1 µg was added as carrier and the bound radioactive globin was eluted by heating the pellet to 90 °C for 2 min in a 25-μl buffer containing 6 M urea (BioRad, electrophoretic purity), 1 M 2-mercaptoethanol (Sigma), 2% Triton X-100, 0.33 mg ml⁻¹ Pyronin-Y. The cells were pelleted and the supernatant applied to a Triton X urea gel The gels were dried, soaked in Enhance (New England Nuclear) and autoradiographed for 4 days. Lane 1, oocytes injected with normal β -globin mRNA; lane 2, injected with β^0 mRNA alone; lane 3, injected with the mutated tRNA^{1.ys} gene only; lane 4, injected with β^0 mRNA and the mutated tRNA^{1.ys} gene. When the β^0 mRNA was injected together with the original tRNA^{1,38} gene, the result was identical to that shown in lane 2. The migration of the α -, β -, α -, and α -globin chains was determined with unlabelled globin markers.

(HGPRT) deficiency are also suspected to be due to nonsense mutations^{29,30}, and nonsense mutations have been detected in Drosophila³¹ and Caenorhabditis elegans^{32,33} by genetic analysis. Transforming cells from such organisms with suppressor tRNA genes may confirm the presence of nonsense mutations in these species and detect such mutations in other human genetic disorders.

Insertion of suppressor tRNA genes can be tested as an approach to gene therapy in β -thalassaemia. While this approach would be limited to β -thalassaemias due to nonsense mutations, it has a theoretical advantage over other proposed gene therapies for β -thalassaemia, such as insertion of a normal β -globin gene into thalassaemia cells. In experiments where a cloned β -globin gene was inserted into heterologous cells, the level of β -globin expression was low³⁴. At present, the mechanism that controls normal β -globin gene expression is not understood. In contrast, since tRNAs are essential for protein synthesis in all cells, inserted functional tRNA genes are likely to be expressed, even in differentiated cells such as erythroid cells.

The success of suppressor tRNA gene therapy depends on the efficiency of suppression by the mutated tRNA. If, as in some bacterial and yeast suppressor tRNAs, the efficiency approaches 60% (refs 35, 36), then the gene should significantly contribute to restoring the balance of α - and β -globin synthesis in β -thalassaemia. In addition, the efficiency of suppression of

suppressor tRNAs can vary. It is therefore important to test the effects of multiplicity of gene insertion and the degree of suppression with various tRNAs. We are currently mutating the tRNA^{Gln} gene in a similar manner in order to study the Mediterranean type of β -thalassaemia due to a β ^{39Gln(CAG) \rightarrow UAG} mutation⁵.

Of course, before the use of suppressor tRNAs can be contemplated for gene therapy, their effect on other cell functions must be assessed. An amber-suppressor tRNA could also suppress termination of proteins that utilize the UAG codon as their normal terminator. Although suppressor tRNAs are lethal in certain yeast strains, no information is available on their effects on cells of higher organisms. The availability of a functional suppressor tRNA gene allows us to test for any deleterious effects it may have on mammalian cells.

We thank Dr Rae Lvn Burke for suggesting the use of an ethidium bromide agarose gel to separate the different forms of synthetic M13 products, Drs Michael Smith and U. L. RajBhandary for their advice on mutagenesis, Dr George Stamatoyannopoulos for the antibody against human globin, and Dr Joe Hedgepeth for the GM48 strain of E. coli and J. Gampell for editorial comments. A model for the cosmic creation of nuclear exergy

K.-E. Eriksson*†, S. Islam* & B.-S. Skagerstam†

* Physical Resource Theory Group and † Institute of Theoretical Physics, Chalmers University of Technology and University of Göteborg, S-412 96 Göteborg, Sweden

The exergy of a physical system is the maximum amount of mechanical work that can be extracted from that system so that a system in thermodynamic equilibrium has zero exergy. An old theme in cosmic thermodynamics is that the second law implies that the Universe is running down (running out of exergy) and approaching thermodynamic equilibrium, 'heat death'. However, in the standard model of the early Universe2, at 0.01 s after the big bang the Universe consisted of ordinary matter (nucleons), electrons and positrons, neutrinos, photons and gravitons. The gravitons were decoupled, but the others were in thermodyamic equilibrium. Thus the Universe had already reached the state of heat death, and its exergy was zero. The main problem is, therefore, not to describe the runningdown of the Universe, but to understand its revival. When and how was exergy created, in particular the nuclear exergy, which is transformed into life-supporting light in our Sun? We have studied a model which should represent the nucleon gas of the early Universe quite well. We find that the main creation of nuclear exergy started around 10 s after the big bang, and most of the exergy was created during the first few minutes, 85% during the first hour, and that the process was essentially completed during the first 24 h. The final value of the exergy was 7.72 MeV per nucleon. The consumption of this exergy started much later and takes place in the stars over a time scale of hundreds and thousands of millions of years.

Although the problem of cosmic exergy creation has not been widely discussed, general answers have been given by Tolman³, and later by Layzer⁴ and Landsberg⁵. The solution is that during the expansion of the Universe, the conditions for local equilibrium changed with changing temperature and pressure. The reactions tending towards equilibrium, however, lagged behind, and disequilibrium arose. This does not violate the second law of thermodynamics. If one considers any element $\Delta\Omega$ of the Universe, its entropy ΔS increases, but its maximum attainable entropy ΔS_{max} may increase faster due to the expansion, which thus induces a growing disequilibrium.

Work can be extracted from a system only to the extent that this deviates from equilibrium. Exergy is thus a measure of deviation from equilibrium, of contrast, internally or against

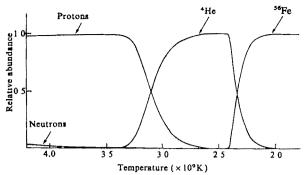

Fig. 1 Relative abundances $P_i^{(0)}$ at equilibrium for the four nucleon states considered in the nucleon gas model.

an external background^{1,6-9}. For instance, in an environment of temperature T_0 , a package of heat ΔQ at temperature T has the exergy

 $\Delta E = \Delta Q \left(1 - \frac{T_0}{T} \right) \tag{1}$

that is here exergy equals energy times a quality factor, which is simply the Carnot factor $1-T_0/T$. As the quality may decrease (with decreasing contrast), unlike energy, exergy is not conserved. Physical processes always go towards increasing entropy which usually means that systems move towards equilibrium and thus towards decreasing exergy. Therefore to attain a state away from equilibrium or to sustain such a state, an exergy input is required.

The totally dominant exergy source of the Earth is the inflow of solar radiation, the value of which derives from its contrast with the ambience of the Solar System, the cold interstellar space. The solar radiation derives from a continuous conversion of nuclear exergy in the interior of the Sun. Our problem is to understand how this exergy arose through the mentioned mechanism. In the nucleon gas of the early Universe, exergy and entropy increased together, and we shall study a simple statistical model for this process.

The era we are considering is dominated by radiation, and the photon gas may be considered as a heat bath which is continuously cooling down. The nucleon gas is always in thermal contact with this bath. Below a certain temperature $(2.0 \times 10^9 \text{ K})$ an iron nucleus (^{56}Fe)—if it could be formed by a coincidence of events (extremely unlikely) or be introduced from outside—would be thermally stable in contact with the heat bath. From then on the nucleon gas may be considered as being overheated, the natural phase at this temperature being a gas of iron nuclei. (The overheating started much earlier, first through an overabundance of neutrons, which decay only slowly. Also for a short period at temperatures near $2.5 \times 10^9 \text{ K}$ (well before helium synthesis) ^4He defines the natural phase of the nucleon gas.)

Several bottlenecks prevent the formation of iron nuclei, the first being the low binding energy of the deuteron. After ⁴He has been formed (through ²H, ³H and ³He) at a temperature below the dissociation temperature of deuterons, density and temperature are already below the values required to sustain continued nuclear fusion reactions beyond helium.

The exergy is thus created, when the nucleon gas makes the transition from the equilibrium state to the overheated state. Some exergy is consumed in neutron decay and in helium formation. In the latter practically all remaining neutrons are absorbed. Helium formation is a relatively rapid process, and in our model it occurs at a sharp instant of time.

In the era under consideration the temperature is still high and the density is sufficiently low to consider the nucleon gas as a non-relativistic Maxwell–Boltzmann gas. Consider again an element $\Delta\Omega$ of the gas. The exergy 10,11 per nucleon is

$$E = kT \sum_{i} P_{i} \ln \frac{P_{i}}{P_{i}^{(0)}}$$
 (2)

where i labels states and where P_i is the actual probability

distribution for one nucleon, and $P_1^{(0)}$ is the probability distribution for one nucleon at thermodynamic equilibrium.

We shall consider a simplified model. As helium forms early in the history of the Universe, and because iron is an end product of nuclear burning, we shall include the ground states of 4 He and 56 Fe in our model but no other composite nuclei. Thus a nucleon may either be a free proton or a free neutron or it may be bound in 4 He or 56 Fe. We shall label these possibilities by an index i of value 1-4.

At low temperatures the statistical factors depend sensitively on the energy levels. This tends to lead to an all-or-none situation. Below the temperature 2×10^9 K, 56 Fe totally fixes the normalization of the $P_i^{(0)}$, and inclusion of other nuclides with tighter binding than 4 He would not change the general picture. Thus it is sufficient to include in equation (2) only 56 Fe and states that are actually occupied. From those latter states we have excluded the transitional nuclides, 2 H, 3 H, 3 He, which are important for the detailed dynamics, but which, due to their relatively low abundance, would change E as a function of temperature only marginally.

At temperature T the equilibrium distribution of the nucleons over the four nuclear states is

$$P_{i}^{(0)} = \kappa r \left(\frac{mc^{2}}{kT}\right)^{3/2} g_{i} A_{i}^{5/2} \exp\left[-A_{i}(\mu(T) - b_{i})/kT\right]$$
 (3)

where g_i is the spin multiplicity of states, A_i is the mass number of the nuclide, and b_i is the average binding energy per nucleon (relative to a free proton); m is the nucleon mass, r is the ratio of photon to nucleon abundance in the Universe, κ is a constant, and $\mu(T)$ is the chemical potential.

Table 1 gives A_n g_i and b_i and further

$$\begin{cases} m = 938.8 & \text{MeV/}c^2 \\ \kappa = \frac{\sqrt{2\pi}}{8\zeta(3)} = 0.351 \end{cases}$$
 (4)

The quantity r is not very well known¹²⁻¹⁴. We shall use the value

$$r = 10^9 \tag{6}$$

The results of our calculation do not depend very strongly on the exact value chosen for this parameter.

The chemical potential $\mu(T)$ in equation (3) is fixed by the overall normalization condition

$$\sum_{i} P_{i}^{(0)} = 1 \tag{7}$$

The derivation of equation (3) follows standard methods of statistical mechanics.

The actual probability distribution is given in Table 2. It changes abruptly when helium is formed, which in our model takes place instantaneously at the temperature

$$T_0 = 1.0 \times 10^9 \,\mathrm{K} \tag{8}$$

The picture would change only marginally if T_0 were changed, and the asymptotic exergy value (7.72 MeV per nucleon) depends on T_0 only through $\gamma(T_0) = \gamma_0$, where $2\gamma_0$ is the fraction of primordial helium, for which we use the value 27% (ref. 2).

In general the neutron fraction is a complicated function, which has to be computed numerically 15-17. The same is true of the relation between temperature and time.

Table 1	Characteristics of the four nuclides considered					
ı	A_iZ_i	g,	b, (MeV)			
1	¹ H .	2	0			
2	¹ n	2	-1.30			
3	⁴He	1	6.43			
4	⁵⁶ Fe	1	8.10			

Table 2 Actual distribution of nucleons over the four nuclides before and after helium formation

								`
	i				$P_{\iota}(T > T_0)$			$P_{i}(T < T_{0})$
,	1	-		-	$1-\gamma(T)$			$1-2\gamma(T_0)$
	2	,	, ,		$\gamma(T)$		•	· 0 ·
	3 ·				0	•		$2\gamma(T_0)$
	4 .	٠.			0			i 0

 $\gamma(T)$ is the neutron fraction.

The exergy per nucleon from equation (2) is now obtained from equation (3) and Table 2,

$$\begin{cases}
E(T) = \mu(T) + |b_2|\gamma(T) \\
-kT \ln \frac{2\kappa r \left(\frac{mc^2}{kT}\right)^{3/2}}{(\gamma(T))^{\gamma(T)}(1 - \gamma(T))^{1 - \gamma(T)}}; & T > T_0 \\
E(T) = (1 + 6\gamma_0)\mu(T) - 8\gamma_0 b_3 \\
-kT \ln \frac{2^{8\gamma_0 - 1}\kappa r \left(\frac{mc^2}{kT}\right)^{3/2}}{\gamma_0^{\gamma_0}(1 - \gamma_0)^{1 - \gamma_0}}; & T < T_0
\end{cases} (10)$$

The equilibrium probability distribution (3) is plotted in Fig. 1. The nucleons dominate completely for $T > 3.5 \times 10^9$ K, and iron dominates for $T < 2 \times 10^9$ K. Helium dominates in an interval around 2.5×10^9 K.

The creation of exergy is shown in Fig. 2. The exergy loss in helium synthesis is ~0.6 MeV. Part of this is compensated for in the following evolution, and the net loss is ~ 0.4 MeV. The final value is given by equation (10) in the low temperature limit,

$$E(0) = (1 + 6\gamma_0)b_4 - 8\gamma_0b_3 = 7.72$$
 MeV (11)

The nuclear burning in stars with iron as an end product takes place relatively late, and several barriers have to be overcome¹⁸. Only a limited fraction of the nucleons in a star are involved in these reactions. Due to the cold environment the relative exergy loss in the transition from nuclear to radiation exergy in a star is small, of the order of 1% or fractions thereof.

At one stage in the expansion of the Universe matter became so disperse that the thermal contact with surrounding matter

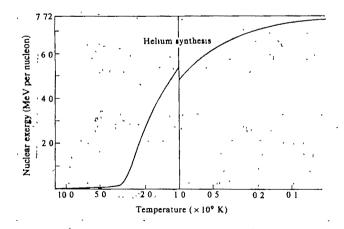

Fig. 2 Nuclear exergy as a function of the cosmic temperature T. Helium synthesis in this model takes place instantaneously at $T = 1.0 \times 10^9$ K. It involves an exergy consumption of around 0.6 MeV per nucleon, one-third of which is compensated for by the subsequent exergy production. This can be compared with the exergy loss of around 10 eV per nucleon some 700,000 yr later, when the electrons condense into atoms.

and radiation could no longer prevent density fluctuations from being enhanced by gravitational attraction. Then a new feature entered the picture. When this happened, matter already dominated over radiation in the Universe. The enhancement of density fluctuations meant that the Universe split on several levels into 'compartments' (protogalaxies and protostars) with relatively little interaction with the exterior. Within each compartment the natural reference state is the equilibrium end state for that compartment. Thus at the time of compartmentalization new exergy was created. For a protostar which is to end up as a white dwarf the nuclear exergy from the first few minutes is augmented by some gravitational exergy (of the order of a few keV per nucleon).

For a more massive protostar which is to end up as a cold neutron star there is also a substantial addition of combined nuclear-gravitational exergy of the order of 40 MeV per nucleon¹⁹. The gravitational exergy here gives the dominant contribution. The heavy elements (heavier than iron) formed in a supernova explosion with a neutron star as the final state for its core, thus have exergy which is mainly of this origin.

For a system large enough to have a black hole as its final state, the exergy per nucleon may be a large fraction of its rest energy20

If matter in the form of nucleons is unstable, as modern elementary particle physics suggests²¹, then matter itself represents a special form of exergy, which was created during the first few microseconds, when an excess of matter over antimatter was developed followed by annihilation of all antimatter and most of the matter²²⁻³¹. Matter as an exergy form is extremely longlived but if the Universe is open and expands for infinity then this exergy will also finally be consumed in nucleon decay (with a half life of $\sim 10^{31}$ yr) and at the end the Universe will consist of ever cooler electrons and positrons (too disperse to annihilate completely), neutrinos, photons and gravitons.

We thank Göran Niklasson and Ture Eriksson for clarifying discussions on the properties of the nuclear gas and on relativistic cosmology. B.-S.S. also thanks J. Prentki and the CERN Theory Division for hospitality. This work was supported by the Swedish Council for Planning and Coordination of Research.

Cygnus X-3 observed at photon energies above 500 GeV

R. C. Lamb*, C. P. Godfrey*, W. A. Wheaton† & T. Tümer‡

* Iowa State University, Ames, Iowa 50011, USA

† Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109, USA

‡ University of California, Riverside, California 92521, USA

We have used the twin 11-m diameter mirrors of the NASA Jet Propulsion Laboratory's solar energy facility to observe highenergy γ rays from Cyg X-3 using the atmospheric Cerenkov technique. Observations of photons with energies above 10¹² eV modulated with the 4.8 h period of the X-ray source have been reported previously by the Crimean Astrophysical Observatory¹⁻⁶ and the Fred Whipple Observatory^{7,8}. We report here data from ~105 air shower events obtained 29 August-6 September 1981 with an approximate threshold energy of 500 GeV. A positive signal with an amplitude of 10.9 ± 2.5% of the background cosmic ray rate appears near phase 0.6 of the 4.8-h cycle, in which phase 0.0 corresponds to minimum X-ray emission. This observation, together with previous Cerenkov detections, indicates that the high energy emission from Cyg X-3 is evolving on a time scale of a few years which suggests a recent origin for the system in its present form.

The JPL solar energy mirrors are located at Edwards Air Force Base, California at a dry desert location at an elevation of 0.7 km. Each mirror was viewed by a single, fast photomultiplier which gave full fields of view of 1.0° and 1.8°. (Requirements of compatibility with the solar research dictated the unequal size tubes.) The mirrors are separated by 24 m. The rate of air shower coincidences between the two mirrors is ~60% of the rate for a single mirror. Preliminary tests with the mirrors in June–July 1981 gave a background coincidence rate of ~4 s⁻¹ for air shower events near the zenith. However, before our August–September run, the focus of one of the mirrors was changed for solar energy purposes to reduce the effective size of the mirror to ~5 m. The data reported here were obtained in conditions in which the background rate at the zenith was about 1 s⁻¹.

Extensive alignment tests and angular calibrations were performed with each mirror using the image information from paraxially mounted television cameras. During observations the pointing of each mirror was monitored and found to be reproducible to better than 0.1°. Data associated with air shower events were recorded magnetically when signals from the two detectors occurred within 50 ns of each other. The pulse height associated with each detector, the time difference between the two signals, and the universal time to 0.1 ms were recorded. In addition singles and accidentals rates were monitored. The accidental rate for most scans was <1%. Analysis of the data offline showed that coincident events were characterized by a peak whose FWHM was ~10 ns, equivalent to a resolving time of ~5 ns. For the data reported here we have selected events with a 'tight' coincidence requirement corresponding to a resolving time of 3.8 ns.

Observations were made in drift scans which typically lasted 33 min, starting 17 min before and ending 16 min after transit. Following the procedure of Danaher $et\,al.^7$, we divided the data from an individual drift scan into three regions: two background regions more than 5 min before and after source transit, and an on-source region. We used an on-source region of 7 min centred at the source transit time. From a sum of the drift scans we determined that the 2nd mag star, γ Cygni, which transited 10 min before Cyg X-3, increased the background rate by $3\pm$

1%; therefore we have deleted data during an interval of 6 min about γ Cyg from our analysis.

The data rate was analysed in 30-s bins. A scan was rejected if: (1) any 30 s interval gave a $\pm 4\sigma$ departure from the mean; (2) the two background observations failed to agree at the 5% level; (3) a χ^2 uniformity test for the run as a whole failed at the 5% level. In addition a Poisson homogeneity test at the 5% level was applied to the data binned in 10 s bins. Of 95 drift scans recorded during the 9 day run, 81 passed all tests.

Figure 1 shows the ratio of the on-source counting rate to the background counting rate corresponding to various phases of the 4.8-h periodicity. Errors have been calculated both experimentally and on the basis of Poisson statistics. For the scans which passed the selection tests there is no significant difference, and the Poisson values are used. For our phase calculation we have used the X-ray parameters of van der Klis and Bonnet-Bidaud⁹. Their quadratic and linear parameters give a difference in phase of 0.04 at our epoch. We have used the quadratic parameters tied to their well determined $T_{\rm min}$ of May-June 1980. If the Crimean values are used then the phases of Fig. 1 are increased by 0.115.

Eight of the 10 phase bins are consistent with no signal. However, in the adjacent phase bins from 0.5 to 0.7 there are 3.1 and 2.9σ excesses, which together constitute a 4.2σ excess which we interpret as a positive detection. If we bin the data in the signal region in bins of 0.05 phase, the ratios and significances for the four bins beginning at 0.5 phase are: 1.04 (0.7σ) , 1.12 (3.2σ) , 1.09 (2.2σ) , and 1.08 (1.9σ) . The 23 scans corresponding to phases between 0.5 and 0.7 have been added together and their sum is shown in Fig. 2a. These data have been fitted to a level background plus a gaussian of variable width and height centred at the transit time. The best fit value of the height is $10.9 \pm 2.5\%$ of the background, equivalent to a 4.4 σ detection. Figure 2b shows the sum of the scans with phases outside of the range 0.5-0.7. The horizontal line corresponds to the average background rate. The flux averaged over a cycle corresponding to the effect is $\sim 8 \times 10^{-11}$ photons cm⁻² s⁻¹ in reasonable agreement with previous detections at higher energies.

The phase of the observed emission, 0.6 ± 0.1 , agrees with the phase typically seen for maximum X-ray emission⁹ and agrees approximately with the 1980 observation of Danaher et al.⁷, after accounting for the different methods of phase calcula-

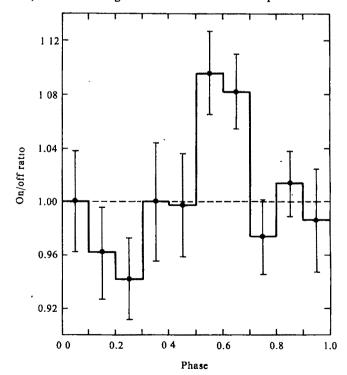

Fig. 1 Phase histogram of the γ -ray emission from Cyg X-3.

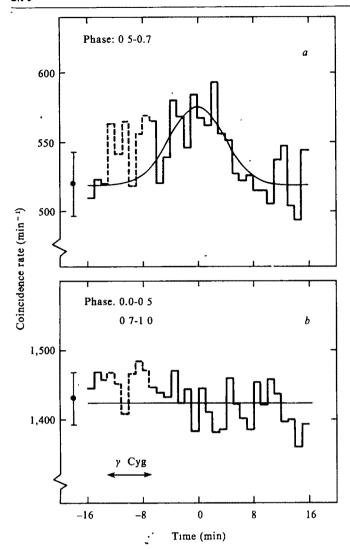

Fig. 2 Coincidence rate in c.p.m. versus drift scan time. The transit of Cyg X-3 occurs at time 0. a, The sum of the 23 scans corresponding to phases between 0.5 and 0.7. The smooth curve is the best fit of a gaussian, centred at the transit, plus a level background. The height of the gaussian is $10.9 \pm 2.5\%$ of the background, equivalent to a 4.4σ detection. b, The sum of the remaining scans. The horizontal line corresponds to the average background rate. For these phases there is no evidence for γ -ray emission from Cyg X-3. The dotted portion of each histogram corresponds to the 6-min interval in which the 2nd mag star, y Cyg, is in the field of view. These data were not used in any of the analyses.

tion⁸. However, the width of ~0.2 cycles seen here may be inconsistent with their results and is inconsistent with the Crimean results which have been interpreted as indicating activity confined to 0.05 cycles^{4,6}. Also, we see no evidence for emission at other phases as observed in some of the earlier Crimean measurements. The disparity in these observations may indicate changes in the characteristics of the high energy emission on a time scale of a few years. These apparent changes and the apparent 100 MeV variability implied by the SAS 2 detection 10 and the COS B upper limit 11 support the view that Cyg X-3 is a system which is rapidly evolving, and that it may have been created in its present form in the recent past. As has been pointed out 12,13, the presence of high energy γ rays favour models with a young pulsar in rapid rotation. If the pulsed fraction increases with energy as in the case of the Crab¹⁴ and Vela¹⁵ pulsars, then future high statistics ground based measurements may be the most promising method of detection.

We thank the staff of JPL Edwards Test Site for cooperation and especially John Woodbury, Terry Hagen, and Jack Whitehead. Characterization of radioactive fallout from pre- and postmoratorium tests to polar ice caps

Minoru Koide, Robert Michel & Edward D. Goldberg

Scripps Institution of Oceanography, La Jolla, California 92093, USA

Michael M. Herron & Chester C. Langway Jr

State University of New York at Buffalo, Amherst, New York 14214, USA

Polar glaciers contain a detailed historical record of artificial radioactive fallout from the atmosphere1-4. The records are continuous and time frames can be introduced with uncertainties of about ±1 yr. We have previously indicated that there may be characteristic nuclide compositions of fallout produced by weapons testing by different countries from records in ice sheets. For example, the testing period dominated by the US activity in the early 1950s produced a markedly low ²³⁸Pu/²³⁹⁺²⁴⁰Pu ratio and a very high ²⁴¹Pu/²³⁹⁺²⁴⁰Pu ratio compared with those resulting from tests dominated the USSR activity in the early 1960s^{1,3,5}. Here we use analyses on a recently collected Greenland ice sheet core to extend these results and find the characteristic ²³⁹⁺²⁴⁰Pu/¹³⁷Cs and ²³⁹⁺²⁴⁰Pu/⁹⁰Sr ratios for these two periods. The atmospheric behaviours of tritium compared with those of other artificial radionuclides are recorded in its fluxes to the polar ice sheets.

From 40-m deep, 7.5-cm diameter firn cores were recovered from Dye-3 (65°11' N, 43°50' W) in June 1980 as part of the joint US-Danish-Swiss Greenland Ice Sheet Program. Density measurements and visible stratigraphical observations were made on each core section. The cores were then stratigraphically correlated and combined to form individual samples for transuranic and fission product analyses representing 2 yr on average. ³H analyses were performed on the yearly samples. The analytical techniques have been described elsewhere¹.

The average accumulation rate, based on ²¹⁰Pb profile in the glacier, is 52 g H₂O cm⁻² yr⁻¹ (Fig. 1a). The inventory of ²¹⁰Pb, corrected for decay to the time of collection, to the Dye-3 site (9.8 mCi km⁻² for the period 1944-80) is similar to that of South Dome, Greenland (63°31.6' N, 44°34.5' W), for the period 1945-75 that we measured previously (10.2 mCi km⁻ ref. 1). A lower ²¹⁰Pb inventory of 4.4 mCi km⁻² is computed

٤

for the Crete, Greenland, Site at 71°07′ N and 37°19′ W (ref. 6). The ²¹⁰Pb derived accumulation rate compares well with the long-term average rate of 49 g cm⁻² yr⁻¹ determined from stable oxygen isotope analysis⁷. The samples cover on average two year intervals with a range of 1–3 yr, based on the ²¹⁰Pb ages (Fig. 1).

The plutonium inventories to the northern and southern hemispheric polar sites indicate a higher contribution from the US dominated pre-moratorium atmospheric nuclear tests compared with the USSR dominated post-moratorium atmospheric nuclear tests (Fig. 1; Table 1) than previously estimated. The moratorium period was from November 1958 to September 1961. On the basis of the total atmospheric bomb yields of these two periods, the ratio⁸ of post- to pre-moratorium testing is around 70:30. On the basis of the accumulated amounts of

plutonium in both Arctic and Antarctic ice sheets, the contributions from the pre-moratorium tests varies between 41 and 64%. The value from three of the four sites clusters about 43%.

On the other hand, the ¹³⁷Cs and ⁹⁰Sr results (Table 1) accord with the 70:30 ratio from the bomb yields. This was expected because ¹³⁷Cs and ⁹⁰Sr are fission products whereas Pu is not. Pu production does not necessarily correlate with total bomb production as it is also dependent on the type of weapon construction.

The integrated fluxes of ²³⁸Pu and ²³⁹⁺²⁴⁰Pu are about a factor of two lower in the Dye-3 Greenland sites compared with those of the South Dome Greenland site. The fluxes are: ²³⁸Pu, 0.003 and 0.006 mCi km⁻²; and ²³⁹⁺²⁴⁰Pu, 0.27 and 0.7 mCi km⁻². This situation may arise from unique meteorologies associated with the delivery of stratospheric fallout to the two areas, only

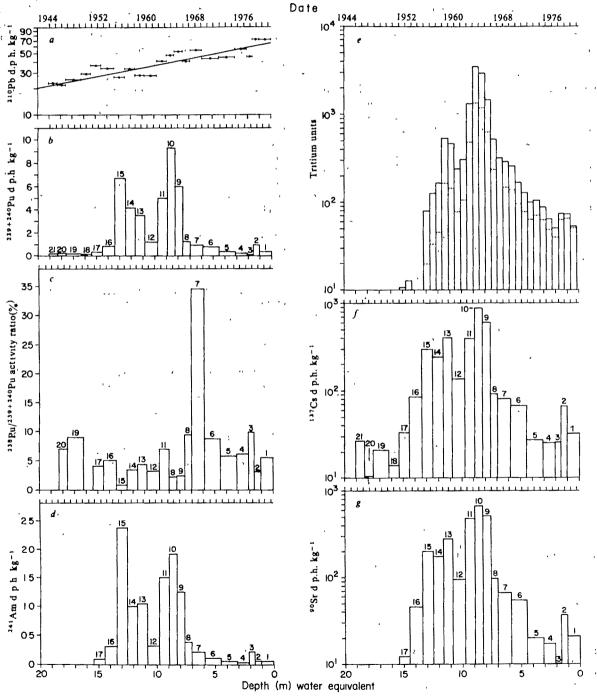

Fig. 1 Radionuclides in the Greenland Ice Sheet at Dye-3 Station. The time scale is derived from the ²¹⁰Pb profile (a). The ²³⁸Pu (c), ³H (e), ¹³⁷Cs (f) and ⁹⁰Sr (g) concentrations are corrected to the time of deposition. The tritium activity observed is indicated by the dashed line in the histogram (e). The average counting errors and their ranges (in parentheses) are: ²³⁹⁺²⁴⁰Pu, 6.8% (2.9-15); ²³⁸Pu, 24% (8-50), intervals from SNAP-9A input 8% (8-14); ²⁴¹Am, 10.4% (4.7-19). For ²¹⁰Pb, ¹³⁷Cs and ⁹⁰Sr, the counting errors were <3%.

a few hundred kilometres apart. This result suggests the site-specificity of the fluxes and the uncertainty in utilizing them as representative of a large area. Lambert et al. found a similar situation with the distribution of for in the Antarctic ice-sheet.

The lowest 238Pu/239+240Pu activity ratio occurs in Level 15,

The lowest 238 Pu/ $^{239+240}$ Pu activity ratio occurs in Level 15, 0.7% (Fig. 1c). This is concordant with the low values of the ratio (<1%) found at the Antarctic sites, J-9 and Dome C, for similar times^{1,3}.

The Arctic ratios of the integrated fluxes (²³⁹⁺²⁴⁰Pu/¹³⁷Cs, ²³⁹⁺²⁴⁰Pu/⁹⁰Sr and ¹³⁷Cs/⁹⁰Sr; Table 1) are remarkably similar for the pre- and post-moratorium intervals to those of the Antarctic site at J-9. These ratios distinctly characterize the pre- and post-moratorium testing: ²³⁹⁺²⁴⁰Pu/¹³⁷Cs, pre-moratorium 0.016 and 0.019, post-moratorium 0.012 and 0.012; ²³⁹⁺²⁴⁰Pu/⁹⁰Sr, pre-moratorium 0.023 and 0.027, post-moratorium 0.013 and 0.011; ¹³⁷Cs/⁹⁰Sr, pre-moratorium 1.6 and 1.5, post-moratorium 1.1 and 0.9. Note that an average post-moratorium activity ratio of ²³⁹⁺²⁴⁰Pu/¹³⁷Cs of 0.012 was obtained from the annual atmospheric data of Richland, Washington (1962–75), New York (1969–75) and Harwell, UK (1972–75)¹⁰. There are no data available for comparison with our pre-moratorium ratios.

The high Pu/Cs and high Pu/Sr ratios for the US dominated pre-moratorium testing period in the 1950s in the Antarctic samples¹ are confirmed here for the Dye-3 samples. Levels 14 and 15 (Fig. 1) correspond to this testing period whose fallout in the Arctic took place primarily between 1955 and 1958. The ratios have values during this period twice those of previous and subsequent years. On the other hand, the Cs/Sr ratio during this period is significantly higher than during the postmoratorium period (Table 1). The weapons debris, introduced to the stratosphere, apparently becomes mixed there in times that are short with respect to a residence time for the particles of the order of 1 yr. Clearly, the polar glaciers will record the fallout without strong distortions due to meteorology or differences in atmospheric chemistry among the different elements. Thus, as well as the low values of the ²³⁸Pu/²³⁹⁺²⁴⁰Pu ratio in the US dominated 1950s testing period we have identified another characteristic of the radioactive debris at this time.

Again, as in the Antarctic ice sheet, the recorded times of arrival of the plutonium nuclides, the caesium and strontium isotopes and the tritium follow a pattern where the transuranics are the first to accumulate, followed by the alkali and the alkaline earth nuclides and then the tritium. The percentages of the contents of nuclides in stratum 15 relative to the total in strata 13, 14, 15 and 16 are: ²³⁹⁺²⁴⁰Pu, 46; ¹³⁷Cs or ⁹⁰Sr, 31; and ³H, 17 (Fig. 1). Our original explanation indicated that the particulate transuranic nuclides have the shortest residence times in the stratosphere and the tritium, in the form of water, has the longest. ¹³⁷Cs and ⁹⁰Sr have intermediate values of the stratospheric residence times. This may relate to their hydro-

philic natures as ions and the stratospheric times involved in their abilities to form an association with waters.

The tritium concentrations in precipitation (Fig. 1e) show a pattern similar to that of ⁹⁰Sr and ¹³⁷Cs. Two distinct peaks are evident corresponding to fusion weapons testing in the mid-1950s and 1961–62. The deposition of tritium in the pre- and post-moratorium time periods is also similar to that of ⁹⁰Sr and ¹³⁷Cs. Roughly 85% of the total tritium deposition occurred in the post-moratorium period at both Dye-3 and J-9. This is due to the high production of tritium from the detonation of fusion devices¹¹.

Figure 2a displays the deposition at Dye-3 relative to that at J-9 on a year by year basis. Four major events are evident from this graph. All events indicate a sudden increase of deposition at Dye-3 relative to J-9. Note that the tritium deposition usually increases at both stations at about the same time, but the increase for Dye-3 is larger. The first peak follows the beginning of fusion bomb testing in the mid-1950s. The second event follows the large test series of 1961-62. The two smaller events seem to correlate with nuclear series of France and the People's Republic of China following the 1963 moratorium. These tests indicate that for all major series, the initial tritium deposition increased most in the northern polar region. After 1-2 yr, the extreme differences in deposition appear to approach a baseline ratio (Dye-3/J-9 deposition) of slightly greater than six. This is close to the difference in the annual precipitation at the two sites (52 cm compared with 8.9 cm) indicating very little difference in the specific activity at the two sites within about 2 yr after a test series. The small difference in specific activity could be accounted for by the higher tritium concentrations found in Northern Hemisphere surface waters¹⁷

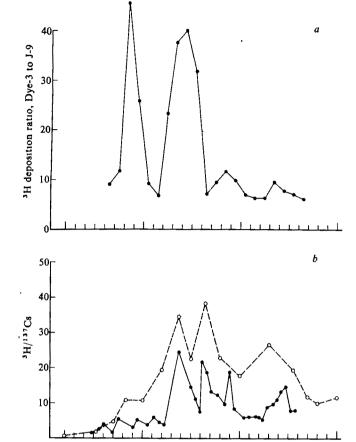

This pattern can be explained as follows. Most nuclear testing produced a large increase in the tritium burden of the northern hemisphere's troposphere and stratosphere. The tropospheric tritium quickly deposited on the Earth's surface while the stratospheric tritium began to mix into the water vapour of the northern troposphere and southern stratosphere. After the initial tropospheric input was deposited, the deposition at Dye-3 was primarily from stratospheric input, although some tritium from re-evaporation was also present. The southern polar troposphere received a much smaller initial tritium input from the nuclear tests. Most of the tritium it received came from the stratosphere. Thus, in less than 1 yr, tritium concentrations at both polar tropospheres were dependent on stratospheric input. From Fig. 2, it appears that transient stratospheric inputs level off in ~2 yr. Due to the short residence time of tritium in the atmosphere, deposition at Dye-3 was ~20 times larger than that at J-9.

Figure 2b, c shows the relative deposition of tritium versus 90 Sr and 137 Cs at both sites. As expected, very little tritium is present relative to these two isotopes in the early nuclear tests.

Following the advent of fusion testing, tritium deposition increased.

These results emphasize the need to carry out similar measurements on mid-latitudinal (alpine) glaciers. We suspect that such glaciers, which exist at all latitudes of the Earth, may hold a detailed record of global artificial radioactivity fallout not found elsewhere and which should contain surprises. With the development of methods over the past decade or so to measure such nuclides at ²³⁹Pu, ²⁴⁰Pu, and ²⁴¹Pu, ²⁴²Cm, and the fission nuclides, their time and space distribution in glaciers should be most revealing about the nature of the weapons and the meteorology of transport. We recognize the difficulties in the identification of appropriate sampling sites where summer melting is negligible or non-existent such that percolation does not smear the record. Approximately 8% of each year's snowfall at Dye-3 was melted and refrozen as ice layers¹³. This suggests

that moderate melting at mid-latitude glacier sites would not seriously perturb the record of radionuclide fallout. We submit that the search for such a record will be rewarding.

This work was supported by grants from the Department of Energy, Environmental Programs, Division of Biomedical and Environmental Research and the National Science Foundation, Division of Polar Programs. H. Rufli drilled the firn cores. We thank Dr T. M. Beasley of Oregon State University for critical comments.

Fission product transmutation effects on high-level radioactive waste forms

W. J. Gray

Materials Department, Pacific Northwest Laboratory, Richland, Washington 99352, USA

The properties of potential nuclear waste forms have been under investigation for more than a decade to ensure their safe handling, packaging, transport, storage, and disposal. Two kinds of high-level radioactive waste (HLW) have received most attention: (1) that which could be produced from reprocessed commercial reactor fuel, and (2) the slightly less radioactive waste from military activities. Both kinds would be converted to solid, nondispersible forms such as glass or crystalline ceramics for disposal. After disposal, self-radiation damage, primarily radiation-induced atomic displacements, can change the properties of these waste forms and possibly increase the chances that radioactivity could be released to the environment. β decay of the fission products causes some displacements but α decay, and the associated recoil nuclei, of the actinide elements produces several orders of magnitude more displacements. Most recent studies on radiation effects have therefore concentrated on α decay¹⁻³. A potentially more important aspect of β decay is the associated transmutation of fission products which usually results in changes of both valence and ionic size, both of which may not be readily accommodated by HLW solids. 137Cs and 90Sr are the two main sources of transmutations, but they have not been studied because of their ~30-yr half lives. The problem has now been circumvented by preparing simulated waste forms and other solids containing 134Cs, which has only a 2-yr half life. This study will not be completed for at least another year, but we report here that results obtained after 2 yr of decay are encouraging in that negligible changes have been observed in the properties of all the materials studied.

Fission products would comprise 40-90% of the HLW stream; the rest would consist of actinides and reprocessing elements. Most (~84%) of the fission products are totally non-radioactive and about half of the radioactive isotopes have half lives $\ge 10^5$ yr. Only $\sim 2\%$ have half lives ≤ 1 yr. Thus, 137 Cs and 90 Sr, which comprise $\sim 6\%$ of the fission products, are the two isotopes of major concern with regard to transmutations. Caesium decays to barium which results in a change in valence from +1 to +2 and a reduction in ionic radius of 20%. Strontium

^{*} Errors listed represent twice the standard deviation of the mean.

decays to zirconium; thus the valence changes from +2 to +4 and the reduction in ionic radius is $\sim 29\%$. However, both ¹³⁷Cs and ⁹⁰Sr have half lives of ~ 30 yr, so it is not practical to use them to study the effects of transmutations.

Two possible ways of studying the effects of transmutations are: (1) to prepare a simulated waste using particular short-lived radioactive isotopes; and (2) to prepare a waste form with nonradioactive material and then irradiate it with neutrons to generate suitable short-lived isotopes. The first method would be prohibitively expensive; the second method is feasible with caesium but not strontium because naturally occuring isotopes of the latter have quite small neutron capture cross-sections. In fact, ¹³⁴Cs is the only suitable isotope that can be generated by neutron irradiation. All other elements have neutron capture cross-sections that are too small, the half lives of the radio-isotopes produced are too short or too long, or the decay scheme does not yield suitably large changes in valance and ionic size.

Natural caesium is 100% ¹⁵³Cs, which has a fairly large thermal neutron capture cross-section. Therefore, a reasonable fraction of the caesium can be converted through neutron irradiation to ¹³⁴Cs, which decays to barium with a 2.06-yr half life. However, because ¹³⁴Cs also has a large thermal neutron capture cross-section that yields the very long-lived ¹³⁵Cs isotope, the amount of ¹³⁴Cs produced reaches a maximum rather than continuing to increase with radiation dosage. The high flux isotope reactor (HFIR) at Oak Ridge National Laboratory, Oak Ridge, Tennessee, was the most efficient reactor available to generate ¹³⁴Cs because of its favourable neutron

energy spectrum and very high neutron flux. Calculations showed that a maximum of 20% of the caesium would be converted to 134 Cs during an irradiation period of \sim 100 days.

Seven glasses and ceramics containing caesium were irradiated in the HFIR during the first 3 months of 1979. Immediately following irradiation, all samples were annealed to remove the neutron radiation damage effects that could mask changes caused by subsequent transmutations. The glass materials were remelted at 900–1,000 °C for 30 min, and the crystalline materials were annealed at 1,150 °C for 1 h. Remelting the glasses should remove atomic displacement damage caused by the high-energy neutrons. Whether the crystalline materials were adequately annealed is not known; it was hoped that X-ray diffraction data would answer that question but those results have been unsatisfactory until quite recently.

Calculations showed, and post-irradiation measurements confirmed, that most of the activity in the irradiated samples was due to ¹³⁴Cs. Thus, any changes in properties are due to Cs→Ba transmutations with only a negligible contribution from other radioisotopes.

Post-irradiation measurements also showed that only 12% of the caesium was converted to ¹³⁴Cs rather than the 20% that had been calculated; however, this should be enough ¹³⁴Cs to observe any property changes as the caesium transmutes to barium. Post-irradiation analyses were completed immediately after the samples were annealed and are being repeated at intervals of ~1 yr. X-ray diffraction, optical and scanning electron microscopy, leach tests, and density measurements are

being made to determine changes as the Cs - Ba transmutations

Table 1 lists the materials irradiated, the amount of caesium in each and results of the density measurements. Density results for two non-radioactive reference materials are also included. Three to five measurements were made on each sample. Densities have increased slightly for four of the materials including pollucite. The largest increases are for the two high-caesium glasses, particularly the one without curium. Increases for the other two materials (4 and 7) are statistically significant, but just barely; additional measurements a year or so from now will be required definitely to establish a trend. No measureable change has been found for materials 1, 5, and 8.

Leach results are listed in Table 2. Three samples of each material were leach-tested in May 1979, three different samples of each were leached during April 1980 and so on. The leach tests were done at 90 °C in deionized water for 7 days. Water volume to sample surface area ratios were 30–40 cm; more importantly, this ratio was maintained at a constant value in each leach test of a given material. Following the leach tests, the leachate solutions were analysed for $^{134}\mathrm{Cs}$ activity using a high-resolution γ -ray spectrometer which was calibrated with a $^{134}\mathrm{Cs}$ standard traceable to the National Bureau of Standards.

After the leachate solutions were analysed for caesium activity, the level of radioactivity was reduced by passing the solutions through ion exchange columns to remove the caesium. The solutions were then analysed by inductively coupled plasma spectroscopy for most other cations except alkali and alkaline earths whose concentrations were altered by the ion exchange resins.

Except for the alkali and alkaline earth interferences noted above, only those elements listed in Table 2 were found in the leachate solutions in concentrations above the detection limits. Several results from the second test and one from the first test seem to be in error. If so, then the leach rates of samples 2, 3, 4, and 5 have not changed noticeably. Sample 8 also has not changed much except for a very small decrease in the leach rate of Cs. The leach rates of samples 1 and 7 have increased slightly. However, the increases are relatively unimportant from a waste management point of view as the changes are less than a factor of 10.

Interestingly, density changes were largest for samples 2 and 3 whereas their leach rates have not changed. This is probably because their leach rates are so large to start with that small changes in microstructure makes little difference.

Optical micrographs were taken of the same areas of all seven samples during each of the three post-irradiation examinations. Scanning electron micrographs were also taken during the second round of examinations and compared with electron microprobe results obtained during the first post-irradiation examination. No change in microstructure was found in any of the samples.

X-ray diffraction results have been unsatisfactory until recently when a new shielded diffractometer became operational at PNL. Only the irradiated pollucite has been examined so far, and even those results are quite preliminary. The pollucite still seems to be at least partially crystalline and the lattice parameters have not changed appreciably. These cursory results obtained about 2 yr after irradiation are thus in approximate agreement with electron diffraction results obtained on a pollucite sample about 6 months after irradiation. The new X-ray equipment will allow much more quantitative results to be obtained in the near future, and other samples, particularly the supercalcine, will also be examined.

About 6% of the total caesium had undergone transmutations at the time of the most recent examinations. In the high caesium glasses, this represents nearly twice as many $Cs \rightarrow Ba$ transmutations as would occur in most commercial waste glasses. The other three glasses have experienced 25–50% of the transmutations as would a typical waste glass. But no changes in properties were found that would be of any consequence from a waste management viewpoint. The crystalline materials were also

relatively uneffected. However, the number of transmutations in these materials has been only about 13% of those expected for an actual waste.

Synthesis of a quasi-stable kaolinite and heat capacity of interlayer water

P. M. Costanzo*, R. F. Glese Jr*, M. Lipsicas† & C. Straley†

*Department of Geological Sciences, State University of New York, 4240 Ridge Lea Road, Amherst, New York 14226, USA † Schlumberger-Doll Research, Ridgefield, Connecticut 06877, USA

The mineral halloysite, in its hydrated and dehydrated forms, has attracted much attention but, in spite of much careful X-ray and electron diffraction work, and electron microscopy, NMR and IR spectroscopic studies, there remain many questions about the crystal structure of the layers, their stacking. as well as the position, motion and bonding of the water molecules (in the hydrated form) to each other and to the surrounding silicate layers. The difficulties associated with studying halloysites are principally due to the great variability observed in natural samples2 and, in the hydrated form, the existence of substantial amounts of pore water in addition to interlayer water. We have attempted to simplify the former difficulty by synthesizing a 10-Å hydrate similar to halloysite-10 Å (ref. 3) starting with a well characterized, crystalline kaolinite from Georgia. Here we report the successful synthesis of a 10-A hydrate which is stable at reduced temperatures and contains no pore water. With this material we have measured C_p for the interlayer water between 110 and 270 K.

The question of the nature of the water in fully hydrated halloysite (designated here as halloysite-10 Å) is of great interest as it can serve as a model for water absorbed on silicate surfaces. In principle, it should be relatively simple to determine the chemical and physical properties of this water because there are few, if any, cations present and there is a much smaller net electrostatic charge on the clay layers than is found among all other hydrated layer silicate minerals. Natural hydrated halloysites must be kept in contact with liquid water or they rapidly dehydrate. The existence of large amounts of pore water makes it very difficult to study the properties of the interlayer water. Our approach has been to synthesize a dihydrate (Al₂Si₂O₅(OH,F)₄·2H₂O) starting with well characterized kaolinites. This guarantees a reproducible material of known morphology, crystallinity and purity. The new synthesis produces a more stable product which is virtually free of pore water and thus represents a considerably simpler material from the point of view of spectroscopic and thermal analysis measurements.

We have previously described³ a means of producing a 10-Å hydrated kaolinite which is indistinguishable from natural halloysite-10 Å samples from Utah. As with the natural mineral,

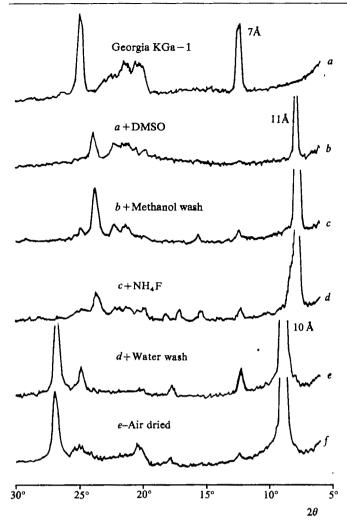

Fig. 1 X-ray diffractograms showing the original kaolinite (a), the intermediate stages of the synthesis (b-d) and the 10-Å product when wet (e) and dried (f). The diffractograms were made with CuK radiation.

this synthetic hydrate must be kept in contact with water to prevent spontaneous dehydration. In spectroscopic studies, such as IR and NMR, it is difficult, if not impossible, to distinguish between the pore water and the intercalated water.

The new synthesis is a variant of the method reported earlier. Figure 1 shows the sequence of steps in terms of the X-ray diffractograms of the starting material, the intermediate stages and the final dried product. The starting clay is the Georgia well crystallized kaolinite identified as KGa-1 (ref. 4). The clay is expanded with dimethyl sulphoxide (DMSO) containing 8% water (step b, Fig. 1) after which the intercalate is washed with methanol (step c, Fig. 1). The key step, as before, is the treatment of the intercalate (step d, Fig. 1) with ammonium fluoride (400 mg per g of kaolinite) for a period of several hours at 60 °C. This is followed by repeated water washings to remove the ammonium fluoride and intercalated DMSO. The wet clay is allowed to dry in ambient conditions. Complete loss of pore water may take several days. As reported earlier³, there is probably fluorine replacement of some surface hydroxyls. We are currently determining the extent of this substitution and its influence on hydrate formation.

Thermogravimetric analysis studies indicate a weight loss of 10% between 300 and 500 K. The theoretical weight loss for a dihydrate is 12.2%. Because X-ray diffraction indicates a yield of $\sim 90\%$, the observed weight loss is in good agreement with the expected value. The remaining 10% is clay which has collapsed back to kaolinite. Moreover, thermogravimetric

analysis does not indicate any substantial amount of pore water. The synthetic hydrate is a hard, dry, massive material which will remain fully hydrated for periods of several months if kept in a sealed container at temperatures near 0 °C. It is not stable at room temperature and in fact loses water rapidly beginning at 280 K. Because of its instability at room temperature, we refer to the synthetic material as a quasi-stable kaolinite dihydrate.

To characterize the interlayer water further, we have studied the IR spectrum and taken measurements of the heat capacity (C_p) . A more detailed discussion of these and other experiments (NMR and electron paramagnetic resonance) will be reported elsewhere.

The IR spectra (Fig. 2) were recorded on a Pye-Unicam 3-300 spectrometer with the clay dispersed in a fluorolube mull. The major features of the stretching bands of water and hydroxyls as well as the deformation bands of water are shown along with the corresponding spectra for the starting clay and for a natural halloysite-10 Å. The IR spectrum of the quasistable kaolinite dihydrate is clearly very similar to that of the natural 10-Å material. The greater crystallinity of the Georgia kaolinite starting material and the absence of pore water allow us to discern details in the spectrum of the synthetic hydrate which are difficult to see in the natural material. The broad band centred around 3,400 cm⁻¹ is due to the continuous water layer⁵. In addition, one sees bands at 3,536 and 3,586 cm⁻¹ which have been reported before⁵ but are very clearly resolved in our material. As will be discussed in detail elsewhere, these bands correspond to water molecules attached to di-trigonal sites on the tetrahedral surface of the interlayer space; we refer to these molecules as 'di-trigonal hole' water. The identification of the nature of the di-trigonal hole water has been facilitated by the existence of a kaolinite monohydrate (d(001) = 8.4 Å)which is the dehydration product of the quasi-stable kaolinite-10 Å. Further evidence for the two types of water (di-trigonal hole and continuous monolayer) can be seen in the partially resolved doublet corresponding to the bending mode.

As noted by Cruz et al.⁶, there are only small shifts in the structural OH stretching frequencies between kaolinite and halloysite-10 Å. The same observation is true for the quasi-stable kaolinite dihydrate and its parent kaolinite (Fig. 2). This suggests that the surface hydroxyls are bonded to water molecules in much the same manner that they bond to the oxygens of the adjacent kaolinite layer.

Cruz et al.⁶ reported heat capacity (C_p) measurements of the water in a natural endellite (halloysite-10 Å). Our C_p measure-

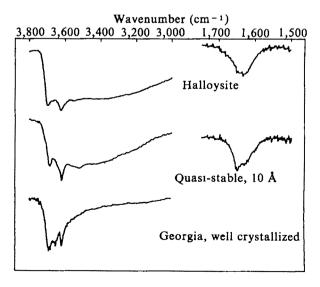

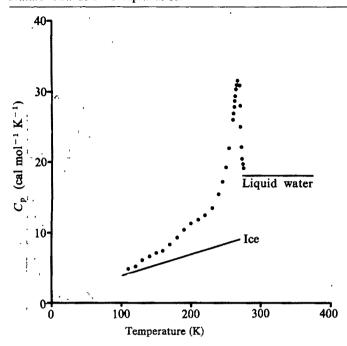

Fig. 2 IR spectra of the Georgia kaolinite (CMS-KGa), the synthetic 10 Å hydrate and a naturally occurring hydrated halloy-site (Utah). The OH stretching and the water bending regions are shown.

A plot of heat capacity versus temperature for the interlayer water of the quasi-stable kaolinite 10 Å.

ments were made on four samples (two between 110 and 190 K and two between 190 and 275 K) of the quasi-stable kaolinite-10 Å using a Perkin-Elmer DSC-2 scanning calorimeter equipped for low temperature operation. The experiment technique was that used by Cruz et al.⁶. The C_p values are plotted in Fig. 3. Internal agreement between different samples is of the order of 2-5% except for the very high C_p values in the vicinity of 265 K where the discrepancy is nearer 10%.

At the lowest temperatures, C_p values for the 10-A water lie very close to values found for ice⁷. Beginning at $\sim 160 \text{ K}$ the C_p values move away from the ice line with a break in slope in the vicinity of 240 K. Above 240 K, C_p rises abruptly to a maximum at 260 K. This peak is reminiscent of the observations of Mraw and Naas-O'Rourke8 on 'freezable' pore water in coal. Cruz et al. did not report this peak in endellite because the upper temperature of their measurements was 255 K. By contrast, C_p for di-trigonal hole water alone, as measured in the kaolinite (8.4 Å) monohydrate, lies very close to the ice line throughout the temperature range studied but shows no discontinuity at 273 K. IR and NMR- $(T_1 \text{ spin-lattice relaxation time})$ measurements as a function of temperature suggest that the heat capacity peak of the kaolinite-10 Å water is associated with an 'order-disorder' type transition in which hole water is transferred to the continuous water monolayers as the temperature is raised. Note that one can readily distinguish two populations of interlayer water in the quasi-stable kaolinite 10 Å.

We thank Dr R. Prost, Dr M. Cruz-Fripiat and Professor J. J. Fripiat for their comments and suggestions concerning our investigation of water in kaolin minerals. Part of the research was supported by a grant from NSF/Sciences to R.F.G.

Volatiles in phyllosilicate minerals

David I. Norman & J. Michael Palin

New Mexico Institute of Mining and Technology, Socorro, New Mexico 87801, USA

Volatiles other than water are known to occur in hydrous ringstructure silicates like beryl and cordierite1.2. However, there has been limited study of volatiles in phyllosilicates. Ammonia has been reported in micas3.4; Banks⁸ measured sulphur in biotite, sericite and chlorite by electron microprobe; and Norman⁶ reported evolution of H₂S and CO₂ when chlorite, sericite and kaolinite were heated to 500 °C. We have studied the thermal evolution of volatiles from phyllosilicates by mass spectrometry. The gases observed were, in approximate order of their abundance, CO₂, H₂S, H₂, SO₂, NH₃, CO, CH₄, N₂, Ar and He. These gases represent 0.35-9 wt % of the volatiles observed; the remainder is water. Step-heating studies indicate H₂S and CO₂ are not generated by the thermal breakdown of sulphide and carbonate minerals. Rather, they are bound within the phyllosilicate structures in a complex way. We show here that gases in chlorite, muscovite and biotite are related to their mode of origin. Phyllosilicates from hydrothermal ore deposits evolve several times more volatiles, principally CO2 and H2S, than phyllosilicates not from ore deposits.

Mineral separates were hand-picked, ground to -70+160mesh, rinsed in distilled water, separated by heavy liquids, treated with warm 10% HCl for 15 min, multiply rinsed and oven dried. Samples were examined for impurities by scanning electron microscope (SEM) with energy dispersive detector, and loaded into a 5×40 mm quartz tube which was placed in an externally heated quartz furnace connected to a vacuum system. The sample was baked at 125 °C while being evacuated to 10⁻⁶ torr. Decrepitation was by heating to 700 °C for 1 h, then 1,100 °C for 1 h. Gases were determined by pressure measurement and quadrupole mass spectrometer; water was measured by weighing. Step-heating samples were heated for 30 min at 100 °C intervals and the evolved volatiles were analysed after each step.

Volatiles evolved on heating belong to five groups, water (including H₂), carbon gases, sulphur gases, nitrogen gases and rare gases. The C-S-N gases vary from 0.01 to 0.33 wt % of the phyllosilicates and analysed and 0.27-9.0 wt % of the volatiles released (Table 1). Within each group of gases, the ratio of oxidized to reduced species depends on the heating procedures. Step-heated samples yield more reduced gases than those heated in two steps.

The gases observed are related to the mode of origin of the mineral. Phyllosilicates from ore deposits evolve several times more gases than those not from ore deposits. In particular, chlorite associated with ore deposits evolves up to 10 times the CO₂ as other chlorite, and micas from ore deposits evolve up to 50 times more H₂S than micas from other environments.

Of particular concern was that the carbon and sulphur gases measured resulted from thermal breakdown of sulphide and carbonate mineral inclusions. Contamination of the mineral separates by sulphide and carbonate minerals is not considered to be serious because contaminate minerals, particularly sulphides, were readily detected by SEM examination and several chlorite samples from rock with a high percentage of sulphide minerals vielded little sulphur gases.

To investigate mineral inclusions and contaminate minerals as sources of carbon and sulphur gases, step-heating studies were done. Evolution of H₂S and CO₂ from phyllosilicate minerals is complex, similar to water (Fig. 1). Hydrogen sulphide is the principal sulphur gas with SO₂ evolution occurring primarily at $T \ge 1,000$ °C.

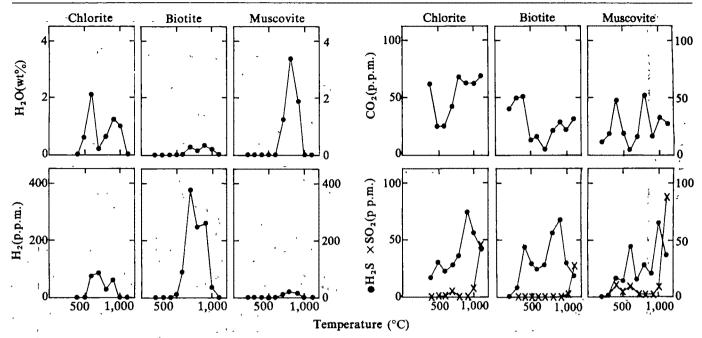

Fig. 1 Evolution of the principal volatiles when three different phyllosilicates were step heated. Chloride is sample CHL2A from a chlorite schist. Muscovite is sample MUS2B from the Bjertnes pegmatite, Norway. Biotite is sample BIO2A from a pegmatite near Mora, New Mexico, USA.

In contrast, when ground sulphides were heated with a low-sulphur chlorite the thermal release curves are simple, SO₂ is the predominant sulphur gas, and considerable SO₂ is generated at temperatures <1,000 °C (Fig. 2). When other mixtures of sulphides, which included FeS, FeS₂, CuFeS₂ and PbS, were heated with chlorite similar results were obtained. Carbon dioxide generated by the thermal breakdown of carbonates similarly has a single thermal release curve which peaks at 700 °C (Fig. 2).

We conclude that the sulphur and carbon gases released on heating phyllosilicates are not the result of mineral inclusions

.

or contaminate minerals because: (1) The thermal release of sulphur gases and CO_2 from phyllosilicates does not resemble the generation of these gases in our experiments. (2) Thermal release curves for H_2S and CO_2 are complex, with several peaks, and are similar to water which is structurally bound in phyllosilicates. (3) Contaminate sulphides evolve more SO_2 when heated with phyllosilicates and the SO_2 is generated at $T < 1,000^\circ$; whereas phyllosilicates evolve mostly H_2S and SO_2 is formed at $T > 1,000^\circ$. (4) Carbon dioxide thermal-release curves have a minimum at the temperatures at which carbonates breakdown; 700-800 °C. (5) Gases bound to surfaces would be

Analyses of step-heated samples (s) and samples from ore deposits (o). Data are presented as the weight ratio of volatile to mineral. NA, not analysed

released at T < 500 °C and hence cannot account for most of the gases observed.

It is unlikely that volatiles other than rare gases occur in the phyllosilicates in the form they are measured. For example, water occurs as the hydroxyl ion. Neither the species which yield the gases observed nor their structural location can be deduced from the data presented or from calculated activation energies. There is evidence that nitrogen occurs as the NH4 ioff bound between silicate layers^{4,7}. Carbon dioxide production has been demonstrated by heating silicate minerals containing elemental carbon⁸; however, there is no reason to exclude the possibility that carbonate or bicarbonate ions might occur in phyllosilicates in a manner similar to ammonia. Our data suggest that water and hydrogen are released from chlorite and biotite at two temperatures by the breakdown of Fe-OH and Al-OH bonds; whereas these volatiles are evolved from muscovite primarily at one temperature by the breakdown of Al-OH bonds. Evolution of H₂S and CO₂ is not analogous to water in that they have multiple-peaked, thermal-release curves for muscovite. This suggests that H₂S and CO₂ are not structurally bound in the same way as water, although the temperature of gas release suggests bond energies for H₂S and CO₂ the same as the hydroxyl ion.

The association of high amounts of volatiles in phyllosilicates with ore deposits suggests that volatiles in phyllosilicates have

a potential use as an exploration tool for ore mineralization. The ubiquitous presence of sulphur in phyllosilicates may be an unrecognized source of reduced sulphur. This reduced sulphur could be an important source of sulphur in the genesis of some ore deposits. Also, phyllosilicates, either during formation or through ion exchange processes, could be important in the inorganic reduction of sulphate.

Seismicity and rheology of subducted slabs

Rinus Wortel

Vening Meinesz Laboratory, Instituut voor Aardwetenschappen, University of Utrecht, Budapestlaan 4, 3584 CD Utrecht, The Netherlands

Since the incorporation of the inclined zones of intermediate and deep seismic activity into the theory of plate tectonics1,2 it has been generally accepted that earthquakes with focal depths ≥100 km occur in subducted slabs of (predominantly oceanic) lithosphere. Yet our understanding of the processes which generate intermediate and, in particular, deep earthquakes is still incomplete. This is largely due to our limited knowledge of the rheological behaviour of subducted oceanic lithosphere at depths between ~100 and 700 km. However, recently considerable insight has been gained into the rheology of oceanic lithosphere in near-surface conditions and I investigate here whether the seismic activity at depths >100 km can be understood on the basis of this information. I first present results of temperature calculations performed for all subduction zones for which adequate data on seismicity, relative plate motion and age of the descending oceanic lithosphere exist. Subsequently, I adapt the temperature conditions governing the rheology near the surface by including depth-dependence. This leads to a depth-dependent critical temperature $T_{cr}(z)$ above which the subducted lithosphere cannot sustain the stresses necessary to generate seismic events. Seismicity data and calculated temperature versus depth relationships are in good agreement with the rheological model predictions. This implies that the absence of seismic activity at depths ≥700 km should not be interpreted as direct evidence for the hypothesis that the 650-km discontinuity in the mantle acts as a barrier to vertical motion of subducted slabs.

McKenzie³ and Griggs⁴ investigated whether the maximum depth of earthquakes in subducted slabs is determined by a critical temperature. Although their results lent qualitative sup-

port to such a relationship their studies were based on limited data and hampered by great uncertainties concerning important geophysical parameters. Vlaar and Wortel⁵ have shown, from observational data, that the maximum depth of earthquakes in subduction zones increases with increasing age of the downgoing oceanic lithosphere. Meanwhile, results of modelling the thermal structure of oceanic lithosphere^{6,7}, description of global relative plate motion⁸ and the widespread identification of magnetic anomalies in the oceans have provided the basis for more extensive and reliable calculations of the thermal structure of subducted slabs. The calculations reported here are based on McKenzie's approach³ in which a slab is assumed to sink in a mantle with an adiabatic temperature gradient. The adiabatic temperature distribution in the (upper) mantle below the lithosphere corresponds with a constant potential temperature $T_{\rm m}^{(p)}$ (see ref. 3), for which we take $T_{\rm m}^{(p)} = 1,200^{\circ}$ C. Crough's model for the thermal evolution of oceanic lithosphere, with a temperature of 1,200 °C at the base of the lithosphere and fitted to bathymetry and heatflow data⁶, was used to calculate the age-dependent initial temperature distribution and thickness of the downgoing slab. This model implies an increase in lithospheric thickness from near-zero at a spreading centre to 101 km for 100 Myr old lithosphere. Apart from conduction and adiabatic compression the latent heat associated with the olivine-spinel phase change¹⁰, resulting in an increase in temperature of 135 °C, was taken into account.

Several aspects of McKenzie's analytical model were critically examined by using a finite difference version of the heat conduction equation. Among these was the use of a constant thermal conductivity and the assumption of stationary input of the subduction process (constant lithospheric age at the trench). Model calculations with temperature-dependent thermal parameters as given by Schatz and Simmons¹¹ seemed to yield solutions which very closely agree with those for a constant diffusivity $\kappa = 0.9 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$. The maximum difference in minimum temperature (in °C) was ~2%, the calculations with temperature-dependent parameters giving the lower values. The constant value $\kappa = 0.9 \times 10^{-6} \,\mathrm{m}^2 \,\mathrm{s}^{-1}$ was used in the final calculations. Several subduction zones exhibit temporal variations in the age of the downbending lithosphere at the trench,

Table 1 Subduction zones and parameters

	Zone	Age (Myr)	$v_{\rm c}^{(n)*}$ (cm yr ⁻¹)	Length (km)	Dip (deg)	Depth (km)	Ref.†

^{*} Component of convergence rate normal to plate contact.

for example, Sumatra, the Aleutians and South America (see ref. 12). Investigating the effect of these variations showed that the temperature distribution at a certain downdip distance in the subducted slab depends primarily on two parameters of the part of the lithosphere involved—the temperature distribution, or age, at the time of initial downbending at the trench and the time elapsed since it started to descend. Whether adjacent parts of the slab were slightly older or younger at their times of onset of subduction is negligible.

All subduction zones for which adequate data on slab geometry (length, dip and maximum depth of seismic zone), relevant plate kinematics and age of the downgoing slab were available are listed in Table 1. The main reason for rejecting subduction zones was lack of knowledge of real convergence rates, usually because of the unknown contribution of back-arc spreading. The relative plate motions given by Minster et al. and Jordan⁸ were used instead of the more recent results by Minster and Jordan¹³ because the former are more representative of the timespan which is involved in the subduction process. Age data were primarily taken from ref. 9. Seismicity data were taken from regional studies which report high-quality hypocentre locations (references are given in Table 1). See ref. 14 for a more extensive account of the data selection and the thermal modelling procedure.

In the present context the most relevant feature of the temperature distribution in a subducted slab is the minimum temperature at the depth of the deepest earthquake. For the subduction zones listed in Table 1 these temperatures are plotted in Fig. 1 as a function of depth. Owing to the nature of the thermal evolution of oceanic lithosphere the temperature distribution in a young descending slab is more sensitive to absolute errors in lithospheric age than the distribution in an old slab. For subducted slabs 35, 65 and 120 Myr old, an error of $\pm 10\,\mathrm{Myr}$ in age results in errors in minimum temperature at the deepest earthquake foci of ±55 °C, ±25 °C and ±15 °C respectively (apart from the latent heat contribution of the olivine-spinel phase change). The uncertainty in the age of the downgoing slab in zones 7-11 (see Table 1) results only in an uncertainty of ±30 °C with respect to the values plotted in Fig. 1, which were calculated for an age of 120 Myr. Reliable calculations can only be made for continuous slabs. Therefore, the deep earthquakes beneath New Zealand (zone 11) and South America (zones 13, 14, 15), which probably occurred in

detached pieces of lithosphere, were not taken into account. In general, Fig. 1 displays a distinct increase in minimum temperature with depth. Molnar et al. 15 have produced results which are qualitatively fairly similar to those in Fig. 1, but they did not concentrate on testing the conditions that govern the extent of a seismic zone.

The basis of the present discussion is that the rheology of the seismically active part of a slab must allow for the accumulation of stresses which are relaxed in the process of an

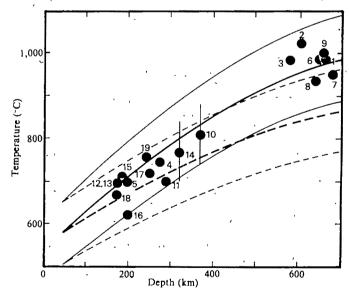

Fig. 1 Minimum temperatures at the depths of the deepest earthquakes in subduction zones: numbers refer to the zones listed in Table 1. The vertical bars for zones 10 and 14 reflect the uncertainty as to whether the olivine-spinel phase change has taken place. The points for zones 12 and 13 coincide. The thick solid curve represents $T_{\rm cr}$ (critical temperature above which no earthquakes are generated) as a function of depth, based on Stacey's mantle solidus. The thinner upper and lower solid curves indicate the range for $T_{\rm cr}$ resulting from uncertainties in the temperature at the depth of the 'calibration event' near the Tonga trench (see text). The thick dashed curve represents an alternative $T_{\rm cr}$ curve based on equation (10); the two other dashed curves indicate the uncertainty range for this $T_{\rm cr}$ curve.

[†] References from which seismicity data (downdip length, dip and maximum depth) were taken. Length is measured from the trench to the depth of the deepest hypocentres. The dip angle is measured in the intermediate depth range.

 $[\]ddagger n_1 \rightarrow n_2$ means that the present age at the trench is n_1 Myr and the deepest seismically active part of the slab was n_2 Myr old at the time it started to descend. n_2 was used in the thermal calculations.

From ref. 32.

Zones 10 and 11 correspond with Hamilton and Gale's 37 sections B and C respectively

Including a correction of 200 km for the excessively long accretionary prism.

earthquake. The problem is approached by relating the seismicity in the descending slab to relevant near-surface conditions and phenomena of which more direct observations are available. Two types of observation are considered: (1) observations of the geometry of the bending lithosphere near the trenches (in combination with those on seamount loading)^{16,17}, and (2) observations of the seismic activity of the oceanic lithosphere just before the latter starts to descend into the trench^{18,19}. Both data sets bear on the rheology of the lithosphere at the surface and, hence, on the input of the subduction process (section A in Fig. 2).

The rheological model used by Caldwell and Turcotte¹⁶ for the bending and seamount loading is simpler than that used by Bodine *et al.*¹⁷. In view of the many uncertainties attached to the slab's rheology at greater depths it seems more appropriate to base the analysis on Caldwell and Turcotte's¹⁶ model. These authors assumed that below a certain temperature T_{\bullet} elastic stresses do not relax on geological time scales whereas at temperatures above T_{\bullet} stresses are relaxed by creep processes. In this spirit Caldwell and Turcotte¹⁶ studied the rheology of oceanic lithosphere, using power-law creep behaviour for olivine appropriate for differential stresses below 2 kbar (ref. 20)

$$\frac{\mathrm{d}s_{\mathrm{p}}}{\mathrm{d}t} = C\sigma^{3} \exp(-A/RT) \tag{1}$$

 $\mathrm{d} s_\mathrm{p}/\mathrm{d} t$ is the creep rate, σ the differential stress, T absolute temperature, R the universal gas constant, A an activation volume and C a constant. By using a Maxwell-type of viscoelastic model they derived an expression for T_e :

$$T_{\mathbf{o}} = A/\{R \ln \left(\frac{2}{3}EC\tau_{\mathbf{R}}\sigma_{\mathbf{0}}^{2}\right)\} \tag{2}$$

where E is Young's modulus and τ_R is the time for the stress σ_0 , applied at t=0, to relax to one-half its original value. Using Goetze's²⁰ values A=122 kcal mol⁻¹ and C=70 bar⁻³ s⁻¹, and $E=6.5\times 10^{10}$ N m⁻², for $0.1<\sigma_0<2.0$ kbar and $0.1<\tau_R<10.0$ Myr T_e varies from 660 to 840 °C. These temperatures are in good agreement with those derived, from studies of lithospheric bending¹⁶, for the base of the elastic upper part of the lithosphere and also for the depth corresponding with Bodine et al.'s¹⁷ mechanical thickness H of the lithosphere (defined as the depth below which the yield strength of the lithosphere is <500 bar).

The usual way²¹ to include depth- or pressure-dependence in equation (1) is to put

$$\frac{\mathrm{d}\varepsilon_{\mathrm{p}}}{\mathrm{d}t} = C\sigma^{3} \exp\left(-gT_{\mathrm{m}}/T\right) \tag{3}$$

where g is a constant and T_m the melting temperature (in K) at the appropriate depth or pressure. The analogue of equation (2) is then

$$T_0 = gT_{\rm m}/\ln\left(\frac{2}{3}EC\tau_{\rm R}\sigma_0^2\right) \tag{4}$$

For $0.1 < \tau_R < 10.0$ Myr and $0.1 < \sigma_0 < 2.0$ kbar we find

$$55.2 < \ln \left(\frac{2}{3}EC\tau_{\rm R}\sigma_0^2\right) < 65.8 \tag{5}$$

As a good approximation, we may write instead of equation (4):

$$T_o \simeq \alpha T_m$$
 with $\alpha = g/60$ (6)

Briefly, studies of the bending of oceanic lithosphere have shown that the rheology of the lithosphere is strongly temperature dependent. The temperature-dependence is controlled by the ratio $T/T_{\rm m}$.

The second data set comprises precise depth determinations of earthquakes associated with the bending of the lithosphere near the trenches given by Chapple and Forsyth¹⁸ (see also ref. 19). From this data set we can derive an estimate of the maximum temperature at which deformation of the lithosphere (in near-surface conditions) produces earthquakes. This maximum temperature is found for the deepest event of the data set, which occurred east of the Tonga trench at a depth

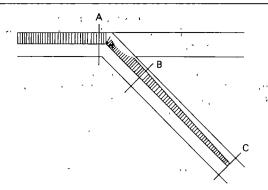

Fig. 2 Representation of a subducted slab. Hatching indicates the parts of the downgoing slab which are potentially seismically active. Earthquakes at or near the contact between the descending slab and the upper plate are not considered, in view of their different character. The lithosphere at section A is representative of the input of the subduction process. Section B and C are at the depth of the double seismic zones (about 120-200 km) and at the downdip end of the seismic zone respectively

of 45±5 km. Its focal mechanism solution (horizontal compression) indicates that it took place below the neutral surface of the bending plate. The age of the lithosphere at the Tonga trench, which determines the temperature distribution, is estimated to be in the range 100-140 Myr. According to Crough's 7 thermal model the temperature at the hypocentral depth of this event is 580±70 °C, the error being the r.m.s. error due to the uncertainties in lithospheric age and focal depth. This temperature is taken to be the (empirical) maximum temperature, designated as T_{cr}, at which the deformation of oceanic lithosphere is accompanied by seismic activity. For the analysis of intermediate and deep seismicity we are interested in the depthdependence of $T_{\rm cr}$. Because the compressive 'bending' earthquake occurred in the depth range of the lithosphere of which the rheology is controlled by temperature and on the basis of the results obtained for T_c (see equations (4)-(6)), we assume

$$T_{\rm cr}(z) = \beta T_{\rm m}(z) \tag{7}$$

where $T_{\rm m}$ is the melting temperature and β is a constant. For a chosen $T_{\rm m}(z)$ curve β can be determined from the intercept-value, that is $T_{\rm cr} = 580 \pm 70$ °C at the depth of the Tonga event ($\simeq 45$ km). For $T_{\rm m}$ we first take Stacey's²² composite mantle solidus $T_{\rm s}$. For β we find $\beta = 0.54 \pm 0.04 = \beta_{\rm s}$. $T_{\rm cr}(z)$ and the temperature range resulting from the uncertainty in β are plotted in Fig. 1. As pointed out by Anderson and Minster²³, the composite mantle solidus is representative of the low melting point phases in the polyphase mantle system. The effect of different choices for $T_{\rm m}$ can be illustrated by using, as an extreme alternative, the liquidus for which we take 2,163K at the surface. This yields a lower value of β : $\beta = 0.38 \pm 0.03 = \beta_{\rm i}$. According to Kennedy and Higgins²⁴ the liquidus temperature of the mantle increases more rapidly with depth than the solidus temperature, although in the upper mantle down to 700 km this effect may not be very pronounced. Thus

$$\frac{\mathrm{d}T_{\mathrm{l}}}{\mathrm{d}z} \gtrsim \frac{\mathrm{d}T_{\mathrm{s}}}{\mathrm{d}z} \tag{8}$$

But, because $\beta_1/\beta_1 \approx 0.7$, we have

$$\beta_1 \frac{\mathrm{d}T_1}{\mathrm{d}z} < \beta_1 \frac{\mathrm{d}T_2}{\mathrm{d}z} \tag{9}$$

The upper bound of the temperature range for $T_{cr}(z)$, based on Stacey's mantle solidus, is taken as an upper bound for all T_{cr} curves to be considered. A lower bound can be constructed by taking

$$\frac{\mathrm{d}T_{\mathrm{cr}}}{\mathrm{d}z} = \beta_1 \frac{\mathrm{d}T_{\mathrm{s}}}{\mathrm{d}z} \tag{10}$$

The T_{cr} curve based on equation (10) is also plotted in Fig. 1 (thick dashed curve). The two other dashed curves (upper and lower) indicate the range of T_{cr} resulting from the uncertainty

In the downbending lithosphere near the trench the minimum temperature is clearly below T_{cr}. From numerical model calculations I infer that, for relevant parameter values, the minimum temperature T_{\min} in a subducted slab satisfies

$$\frac{\mathrm{d}T_{\mathrm{mm}}(z)}{\mathrm{d}z} > \frac{\mathrm{d}T_{\mathrm{cr}}(z)}{\mathrm{d}z} \tag{11}$$

for both T_{cr} curves shown in Fig. 1. Because $T_{mm}(z)$ depends on the initial temperature distribution (or age) of the downgoing slab, the direction and rate of plate convergence and the dip of the slab, the depth at which $T_{\text{min}}(z) = T_{\text{cr}}(z)$ varies from one zone to another. Whether the downdip extent of a seismic zone is determined by a limiting temperature T_{cr} can now be checked at the level of section C in Fig. 2: the minimum temperatures at the depths of the deepest foci in continuous subducted slabs, plotted as a function of depth, should delineate the T_{cr} curve. Figure 1 shows that all calculated minimum temperatures fall between the upper and lower bounds derived for T_{cr} . Even with the more restricted range belonging to Stacey's solidus curve the temperatures are in very good agreement. Note that takinginto account the effect of stress level variations [see equation (5)] or errors in the melting point curve would broaden the model range for T_{cr} .

An additional check of the model (seismic activity confined to regions with $T < T_{cr}$) can be made at the level of section B in Fig. 2 (120-200 km depth), where detailed hypocentral location procedures have revealed a double seismic zone²⁵⁻²⁷. The distance between the two parallel zones varies from ~25 km for the Aleutians²⁵ to 30-40 km for the Kuriles²⁶ and Honshu²⁷ The temperature distributions I have calculated for the subducted slabs in these regions show cold zones ($T < T_{cr}$) with thicknesses exceeding the above cited values by 5-10 km.

Therefore, I conclude that the gross features of subduction zone seismicity at depths between ~100 and 700 km are adequately explained by a model in which seismic activity is confined to those parts of the subducted slabs which have -temperatures below a depth-dependent critical value T_{cr}

For many years, deep seismic activity has influenced debates about the depth extent of mantle convection²⁸⁻³¹. From the results reported here I conclude that the absence of seismic activity at depths >700 km as such should not be considered as direct evidence for the hypothesis that subducted slabs cannot penetrate the 650-km mantle discontinuity.

On the basis of our knowledge of the rheology of oceanic lithosphere and melting temperatures in the mantle, the maximum depth of earthquakes can be understood in terms of thermal assimilation or rheological de-activation.

Arguments involving the depth variations of earthquake magnitudes or energy release have not been used here in order to avoid confussion; the slab's rheology as considered here must provide basic conditions for generation of earthquakes, whereas magnitudes and energy release also depend on the forces acting on the slab and the physical mechanism of an earthquake.

I thank Professor N. J. Vlaar and Dr S. Cloetingh for discussions and comments and Dr D. W. Forsyth for a preprint.

The island of New Guinea, geologically and structurally part of the Indian-Australian plate^{1,2}, is shown on continental reconstructions of the Permian globe as forming the northeastern part of the supercontinent of Gondwana^{3,4}, facing a large Tethys Ocean to the north. The existence of an ocean separating South-East Asia from Gondwana by some 45° of latitude during the Permian has been widely disputed because of the strati-graphical, structural⁵⁻¹⁰ and palaeontological¹¹⁻¹⁴ links between the regions. Palaeontological comparisons of New Guinea and Asia are essential for testing whether or not South-East Asia was a part of Gondwana during the Permian^{15,16}. We now give an account of the first, diverse, reliably dated, Permian articulate brachiopod fauna to be discovered from the island of New Guinea. This fauna is interpreted as reflecting the geographical proximity of Thailand and Irlan Jaya during the late early Permian.

Reports of Permian marine faunas from Papua New Guinea^{17,18} have been shown to be erroneous¹⁹, the faunas being Triassic in age. Previous collections of late Palaeozoic marine faunas from Irian Jaya have been inadequate for precise dating and have provided only a generalized Permo-Carboniferous age¹. The new collections, from the Birds Head region of Western Irian Jaya, are from four localities within the Aifat Formation of the Aifam Group, outcropping on the Taminabuan 1:250,000 sheet area²⁰. The Aifat Formation is some 1,100 m thick and consists chiefly of dark calcareous shale and marl with limestone intercalations. Three of the localities have brachiopod faunas which are remarkably similar to those from the Rat Buri Limestone of Thailand^{20,21} of late

Baigendzhinian (latest Artinskian)21 or early Kungurian22 age. They also have some links with brachiopod faunas of Western Australia and Bitauni, Timor. The fourth locality has yielded a fauna, sharing no species or genera in common with the other three localities, which contains a species of the rare chonetacean Quinquenella that is morphologically close to a Western Australian species23 of the genus. This comparison is used to date the Irian Jaya species as late Baigendzhinian. The locality, in addition to Quinquenella, has only yielded fragmentary spiriferid brachiopods which are unidentifiable at this stage. Of the 14 genera from the Irian Jaya fauna, 13 are present in the Rat Buri Limestone faunas; 11 species are morphologically close between the two regions (Table 1).

Most of the classic Permian brachiopod faunas of Timor, such as the Basleo fauna, are much younger than the Irian Jaya and Thailand faunas21. An exception is the Bitauni fauna which exhibits some similarities with the Irian Jaya fauna (such as representatives of Stereochia and Stenoscisma close to Stenoscisma sp. nov.) and the Thailand and Western Australian late early Permian faunas²¹ (such as the presence of Retimarginifera). However, the Bitauni fauna has not been fully described thus preventing detailed comparison. Furthermore, the tectonic setting of the Bitauni fauna is confused because the Timor limestones occur as lenses in the Tertiary Bobonaro Scaly Clay Olistostrome. They have been interpreted as being allochthonous tropical limestones from the northern margin of Tethys24. However, limestone is known from the Australian north-west offshore shelf2 and the Timor limestone faunas are subtropical, not tropical, and show greatest taxonomic affinities to the faunas of northern India and north-west Australia2. The Timor limestones are probably of northern Gondwanan affinity². Links between the late early Permian brachiopod faunas of Thailand and Western Australia, although previously considered to be minimal25, are becoming more apparent as the faunas of Western Australia become better known26. Similarities between Western Australian and South-East Asian Permian molluscan faunas are also significant²⁷

A Permian geographical position for Thailand close to that of Irian Jaya and hence to the northern margin of Gondwana is a possible explanation of these faunal links and the mixed Cathaysian-Glossopteris Permian flora from Thailand that has previously been explained by parallel evolution28. The mixed Permian floras of Thailand and Irian Jaya1 were apparently on the northern fringe of the Gondwana Glossopteris Floral Realm. The Irian Jaya Glossopteris occurs in stratigraphically concordant sediments above the Aifat Formation. The source of the Permian rock sequence of the Birds Head Region is most probably the large area of basement (Kemum Formation) exposed to the north of the outcrops of Permian rocks. The Kemum Formation of Silurian age, is an autochthonous

sequence within the Birds Head Region. A palaeomagnetic investigation of the Birds Head Region is being undertaken by the Bureau of Mineral Resources, Geology and Geophysics.

The new palaeontological evidence presented above supports the incorporation of much of South-East Asia onto the northern margin of Gondwana 10. Permian oceanic Tethys appears to have been north of Southern Thailand, because systematic analysis of the brachiopod fauna has indicated ease of migration between Southern Thailand, Timor, Irian Jaya and Western Australia of closely related species in the late early Permian2 Articulate brachiopods appear to have a free-swimming larval stage of a few hours or days29. This limiting factor, in addition to latitudinal temperature zones and presumed surface currents of the Permian oceans³⁰, would have been a major obstacle to brachiopod migration across a vast Tethys ocean. While several Permian brachiopod genera do exhibit a disjunct distribution, occurring in both Gondwanan and Boreal faunas31, the similarity at the species level between the Irian Jaya and Thailand faunas apparently reflects the geographical proximity of the two regions. The similarity of species seems to imply a relatively narrow latitudinal spread for Irian Jaya and Thailand during the late early Permian, possibly within 5°-10°, because species may range widely along latitudes but they tend not to range far across latitudes32

We thank Dr H. M. S. Hartono, the director, Geological Research and Development Centre, Bandung, Indonesia and the director, Bureau of Mineral Resources, Australia for permission to publish, and Dr S. K. Skwarko for continued advice.

Lateglacial and early Flandrian chronology of the Isle of Mull, Scotland

M. J. C. Walker

Department of Geography, Saint David's University College, Lampeter, Dyfed SA48 7ED, UK

J. J. Lowe

Geography Section, City of London Polytechnic, Calcutta House, Old Castle Street, London E1 7NT, UK

The Isle of Mull, which lies off the west coast of Scotland (Fig. 1), was partially over-ridden by ice from the mainland during the build-up of the late Devensian ice sheet but, in common with the adjacent islands of Rum² and Skye³, supported smaller ice masses, including independent valley and cirque glaciers during the Loch Lomond Stadial^{4,8} (approximately equivalent with the Younger Dryas of Scandinavia^{6,7}). However, although the recent glacial history of Mull is understood, at least in general terms, little is known about the nature and timing of the major environmental changes that preceded and succeeded the Loch Lomond Stadial on the island. We present here pollen-stratigraphical evidence supported by 15 radiocarbon dates which provide new information on landscape changes on the Isle of Mull from the wastage of the last Scottish ice sheet to the early part of the Flandrian period. The radiocarbon dates are of particular significance as they form the basis for the first Lateglacial and early Flandrian chronology for the islands of the Scottish Inner Hebrides.

Four sites have been investigated (Fig. 1). Loch an t-Suidhe (grid ref. NM370215, altitude 30 m OD) on the Ross of Mull and Mishnish (grid ref. NM455565, altitude 120 m OD) to the west of Tobermory are infilled basins which lie outside the area

affected by Loch Lomond Stadial ice, and contain a typical Lateglacial sequence⁸ of organic muds between minerogenic sediments, these deposits in turn being overlain by Flandrian muds and peats. Coire Clachach (grid ref. NM613304, altitude 200 m OD) and Torness (grid ref. NM643333, altitude 110 m OD) are located in Glen More within the mapped limits of Loch Lomond Stadial ice, and these infilled kettle-hole basins contain only Flandrian limnic and terrestrial sediments. At Loch an t-Suidhe and Mishnish, samples for pollen analysis and radiocarbon dating were removed from a deep part of the basins using a piston corer of 5 cm diameter. At the sites in Glen More, however, it was necessary to ensure that the earliest sediments that had accumulated following the wastage of Loch Lomond Stadial ice were being sampled, and thus the infills along a 5 m by 10 m grid pattern were sounded to establish the subsurface contours of the basins9. Cores were then taken from the deepest point. At all the sites, samples for radiocarbon dating were obtained by bulking gyttja material from comparable biostratigraphical horizons in up to six closely-spaced cores, the precise levels from which individual samples were to be taken being determined on the basis of relative pollen counts in each core. In this way, narrow bands of sediment 2-5 cm in thickness could be dated. The radiocarbon dates obtained and the principal characteristics of the dated horizons are presented in Table 1.

Difficulties in the dating of Lateglacial and early Flandrian pollen-stratigraphical records in limnic sediments arise because of the possibility of (1) 'hard water error' particularly in dated samples from newly-deglaciated terrain'; (2) contamination by younger carbon where the sediments have been affected by percolating groundwaters^{12,13}; (3) delayed ice-melt in kettleholes which can produce a basal biostratigraphical record and corresponding radiocarbon dates that postdate regional deglaciation at some sites by hundreds or even thousands of years 14,15; (4) relatively slow rates of sediment accumulation in many basins at times of rapid environmental change which result in poor levels of stratigraphical resolution for the dating of key pollen-assemblage zones¹⁶. There are also uncertainties associated with the radiocarbon method. As many of the potential error sources cannot be quantified at individual sites, it is suggested that the dating of Lateglacial and early Flandrian events within any one area should be based on radiocarbon dates from different biostratigraphical horizons. An indication of the 'true' radiocarbon age of each horizon can then be obtained by taking the mean of the individual values. This procedure is followed where possible for the new radiocarbon dates reported here. In averaging the dates from Mull it is, of course, assumed that no significant time-transgression is associated with the vegetational developments identified at each site, a resonable assumption in view of the relatively small size of the island.

Figure 2 shows the dates listed in Table 1 plotted with one standard deviation about the mean in relation to the principal biostratigraphical and lithostratigraphical horizons. The evidence suggests the following chronostratigraphical framework for environmental changes:

(1) Corylus rise: two dates obtained for this event show remarkably close agreement, averaging ~8,800 yr BP. Radiocarbon dates on the Corylus expansion at sites on the Isle of Skye range from 9,655 to 7,500 yr BP, although the latter age determination was considered to be aberrant 17,18. However, comparable dates to these from Mull have been obtained from sites in Wester Ross $(8,951\pm120 \text{ yr BP}^{19})$ and the Spey Valley $(8,670\pm150 \text{ yr BP})^{20}$. The available evidence points to the widespread colonization by hazel of the Scottish Highlands and the islands of the Inner Hebrides shortly after 9,000 yr BP. The dates from Skye might indicate local exceptions to this generalization, but this requires further examination. The expansion of hazel on Mull appears to postdate that in lowland Scotland by some 300-400 yr (ref. 21).

(2) Juniperus maximum and Betula expansion: the two dates obtained for the early Flandrian Juniperus maximum average \sim 9,600 yr BP, while the single date obtained for the Betula expansion (9,350±70 yr BP) is in good stratigraphical agreement with the former and also with the dates for the later

Corylus rise.

(3) Loch Lomond Stadial-early Flandrian transition: biostratigraphical resolution of the Loch Lomond Stadial-early Flandrian transition in Scottish sites is seldom clear because of the often slow rates of sediment accumulation, and the rapid vegetational changes that occurred between climatic amelioration at the close of the Loch Lomond Stadial and the expansion of juniper scrub. In addition, it is often impossible to develop a chronology based on radiocarbon which differentiates between the individual pollen-stratigraphical phases within this time period. The dates from Mull on all pre-Juniperus horizons above the Loch Lomond Stadial-early Flandrian lithostratigraphical boundary have, therefore, been grouped together. Of the six dates shown in Fig. 2, that from Coire Clachach $(9,530 \pm 80 \text{ BP})$ is clearly aberrant. The others range between $10,000 \pm 70 \text{ yr}$ BP and 10,440 ± 80 yr BP suggesting a mean age of 10,200 yr BP for the establishment of more stable conditions on Mull following the harsh environment of the Loch Lomond Stadial. The dates from Loch an t-Suidhe are considered to be of particular significance. Sedimentation in this basin seems to have been unusually rapid during the Loch Lomond Stadialearly Flandrian transition, and it was possible to obtain three radiocarbon dates (SRR 1800-1802) from biostratigraphical horizons preceding the Juniperus phase. The fact that these dates are closely grouped, internally consistent and in broad agreement with a number of dates from basal Flandrian sediments from other Scottish sites^{22,23} reinforces the suggestion^{24,25} that the transition to more stable environmental conditions in Scotland at the end of the Loch Lomond Stadial occurred well before 10,000 yr BP.

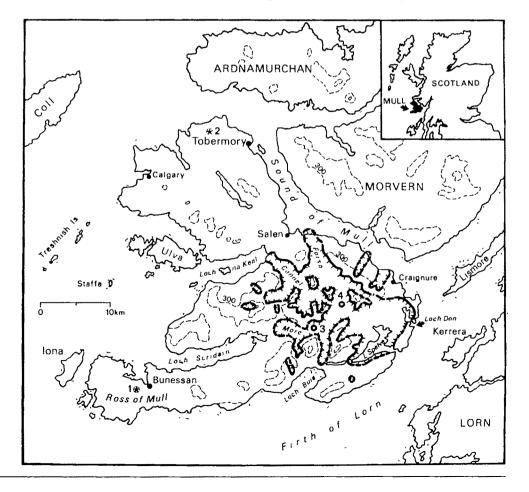

(4) Close of the Lateglacial Interstadial: this event is dated on the Isle of Mull to ~10,700 yr BP on the basis of two age determinations which are in remarkably close agreement. The date is younger than the age assigned to the lower boundary

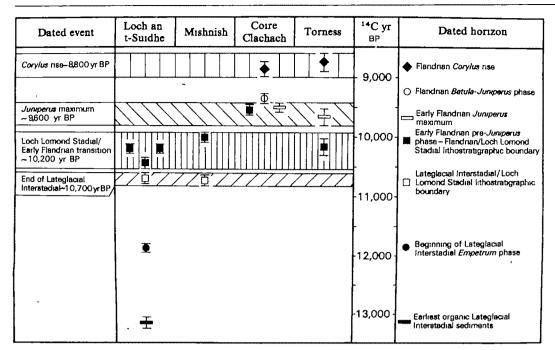

Table 1 Radiocarbon dates from the Isle of Mull

Site	Sample no.	Depth (m)	Thickness (cm)	Date (yr BP)
Loch an t-Suidhe	SRR-1800	7.74	5	$10,200 \pm 70$
Loch an t-Suidhe	SRR-1801	7.80	5	$10,200 \pm 70$
Loch an t-Suidhe	SRR-1802	7.85	5	$10,440 \pm 80$
Loch an t-Suidhe	SRR-1803	8.36	5 .	$10,690 \pm 70$
Loch an t-Suidhe	SRR-1804	8.63	5	$11,860 \pm 80$
Loch an t-Suidhe	SRR-1805	8 77	5	$13,140 \pm 100$
Mishnish	SRR-1806	4.96	' 4	$10,000 \pm 70$
Mishnish	SRR-1807	5.08	4	$10,730 \pm 60$
Coire Clachach	SRR-1594	5.80	5	$8,870 \pm 120$
Coire Clachach	SRR-1595	6.00	5	9.350 ± 70
Coire Clachach	SRR-1596	6.65	5	$9,500 \pm 70$
Coire Clachach	SRR-1597	6.70	5	$9,530 \pm 80$
Torness	SRR-1799	6.65	•2	$8,760 \pm 140$
Torness	SRR-1798	6.67	2	$9,660 \pm 140$
Torness	SRR-1797	6.69	2	$10,170 \pm 150$

of the Younger Dryas chronozone in north-west Europe⁶, and is also younger than age determinations on comparable horizons at several sites on the Scottish mainland 18,20,26. One possibility is that this reflects the more westerly location of Mull and its exposure to moderating maritime influences which could have produced a delayed geomorphological and vegetational response to climatic deterioration, the effects of which were reflected earlier in the pollen stratigraphy at sites on the Scottish mainland. However, it is now generally accepted that climatic deterioration at the onset of the Loch Lomond Stadial was a result of oceanographic changes in the North Atlantic 27,28, in particular the southward migration of the oceanic (and atmospheric) polar front, and therefore climatic deterioration might be expected earlier in the west and not later as is implied by the radiocarbon dates. Yet, at other sites in eastern and central Scotland, dates have been obtained from Lateglacial profiles which are comparable with those reported here from

Fig. 1 The Isle of Mull. Pollen sites: 1, Loch an t-Suidhe; 2, Mishnish; 3, Coire Clachach; 4, Torness. The heavy lines show the limits of Loch Lomond Stadial ice (after ref. 5). Contour interval 300 m.

Flg. 2 Radiocarbon dating of Lateglacial and early Flandrian environmental changes at the four sites on the Isle of Mull.

Mull 18,29,30. Clearly, therefore, there is no consistent spatial pattern in Scottish radiocarbon dates for the close of the Late glacial Interstadial, and it may be that local site factors rather than the macroscale climatic changes were of greater importance in determining the precise nature of lake basin biostratigraphy at the Lateglacial Interstadial-Loch Lomond Stadial transition.

(5) Lateglacial Interstadial: two dates were obtained from the Lateglacial Interstadial deposits at Loch an t-Suidhe. The immigration of Empetrum and, to a lesser extent, Juniperus and Betula, was dated at 11,860 ± 80 yr BP, while the basal organic sediments yielded a radiocarbon age of 13,140 ± 100 yr BP. A comparison between the three dates from the Lateglacial Interstadial at Loch an t-Suidhe (SSR 1803-1805) in relation to their position in the stratigraphical column (Table 1) indicates that the rate of sediment accumulation in the basin during the later part of the Interstadial was almost double what it had been in the earlier stages. Although sedimentation in lakes can be highly variable as a result, for instance, of different rates of inwash and of organic productivity, such a marked discrepancy is unusual, and may reflect errors in one or more of the radiocarbon dates. The age determination of $11,860 \pm 80 \text{ yr BP}$ is difficult to evaluate in the context of the Scottish Lateglacial because of the marked contrasts which appear to have existed in vegetational developments between Mull and the mainland, particularly in respect of the reduced representation of woody taxa in the former area. Moreover, very few dates have so far been published on vegetational changes during the Lateglacial Interstadial in Scotland. The pollen spectra associated with the basal date (SRR 1805) are characterized by a Rumex-Salix-Gramineae-Cyperaceae assemblage and reflect an early stage in plant colonization following the disappearance of the Devensian ice sheet. Although a hardwater error cannot be excluded11, the date of 13,140±100 yr BP is very similar to age determinations on comparable biostratigraphical horizons at sites on the Scottish mainland 18,30-33, and is also in agreement with the inferred date for the replacement of polar by warmer waters around the coasts of western Britain²⁷. If correct, therefore, it would support the suggestion that climatic amelioration at the beginning of the Lateglacial Interstadial in Scotland began around, or even before, 13,000 yr BP (ref. 34).

We conclude with the following framework for environmental change. Wastage of the Scottish ice sheet was followed by climatic amelioration, perhaps around 13,000 yr BP, after which Mull gradually developed a vegetation of Empetrum heath, juniper and birch scrub and open grassland. Climatic deterioration at, or before 10,700 yr BP led to the breakup of the Interstadial vegetation cover, the development of a local ice cap and several separate smaller glaciers in the hills of central Mull, and the establishment of severe periglacial conditions throughout the island. Climatic amelioration around 10,200 yr BP caused the final wastage of the Loch Lomond Stadial glaciers and initiated the early Flandrian plant succession. This began with an Empetrum phase and was succeeded by Juniperus expansion between 9,600 and 9,500 yr BP, the establishment of open birchwoods by ~9,300 yr BP and the immigration of Corylus around 8,800 yr BP. The above chronology is strengthened by the internal consistency of the Mull dates and by the broad measure of agreement between dates from similar biostratigraphical horizons, although clearly the precise timing of events during the early Lateglacial Interstadial remains enigmatic.

This research was financed by the NERC, by the Pantyfedwen Fund of St David's University College, Lampeter, and by the City of London Polytechnic. We thank Dr D. D. Harkness for the radiocarbon dates, Dr R. Cornish, Dr A. G. Dawson, Dr. J. M. Gray and Mr. D. John for assistance with the fieldwork.

M. Whitfield

Marine Biological Association of the United Kingdom, The Laboratory, Citadel Hill, Plymouth PL1 2PB, UK

There has been life on Earth for at least 3,500 Myr but the assumption that a comparable future lies ahead may not be justified. Main sequence stars appear to increase their burning rate as they age. Thus the Sun, if a typical star, can be predicted to have increased its output by 30% since the Earth's origin 4.500 Myr ago¹. The maintainance of an equable climate since life began probably required some means of planetary thermostasis. The Gaia hypothesis proposed by Loyelock and Margulis² included an unspecified biological means for climate control. Walker et al.3 suggests an abiological automatic thermostasis in which the atmospheric abundance of CO2, a greenhouse gas, adjusts to resist the warming tendency of the increased solar flux. Here we discuss possible links between the biological and geological control mechanisms. It is clear that whatever the mechanism, atmospheric CO2 is now close to its lower limit of partial pressure, so the biosphere may soon, in geological terms, be exposed without protection to the predicted progressive increase of solar luminosity.

In spite of the probability of a 25% increase in solar luminosity it is reasonably certain that the Earth's climate has undergone little change since life began. Both the geological record and the persistence of life indicate that neither global freezing nor boiling conditions have ever prevailed. Indeed, the Earth's mean surface temperature has probably never departed from the range 5-50 °C and, contrary to the predictions of simple physics, may have been warmest at the beginning when the Sun was small and has cooled ever since.

Several models have been proposed to account for the Earth's relatively constant temperature. Sagan and Mullen's were the first to suggest that the infant biosphere was warmed by an atmospheric gas which exerted a 'greenhouse' effect by transmitting sunlight while hindering the escape of heat to space.

Although water vapour makes the most significant contribution to the greenhouse effect in the contemporary atmosphere. because of its physical properties water is an unlikely candidate for long-term thermostasis. Its relatively high freezing and boiling points render its blanketing effect prone to positive feedback in the face of extreme temperature excursions. For example, a sudden fall in temperature could result in an increase in the size of the polar ice caps and the seasonal snow fields (thus increasing the efficiency with which radiation is reflected from the Earth) and a corresponding fall in the atmospheric humidity. Both effects could contribute to a further drop in temperature. On the other hand, a sudden rise in temperature would increase the water vapour content of the atmosphere, which would in turn push the temperature still higher. In consequence, the complexities of cloud cover feedback effects over

long periods of time have focused attention on simpler atmospheric models involving other greenhouse gases³⁻⁵

Sagan and Mullen⁵ suggested that the early atmosphere was rich in ammonia and other reduced gases and that these provided the blanket which kept the Earth sufficiently warm for life to emerge. Relatively high partial pressures of ammonia were also seen as essential for the chemical evolution of life and, as ammonia is rapidly photolysed in the atmosphere, a significant inorganic source was sought⁶. Recent work, however, suggests that high partial pressures of ammonia are not essential for the abiological production of amino acids⁷ and that the primordial atmosphere probably contained little ammonia but relatively high partial pressures of CO28. The concept of an early Earth warmed by the blanketing effect of its atmosphere is still therefore feasible but with CO₂ the preferred blanket gas^{4,7}. According to this hypothesis whatever greenhouse gas or other agency kept the young planet warm, it must have been smoothly and actively reduced from then until now; otherwise the mean temperature would have progressively increased with increasing solar heat flux and might by now have exceeded 50 °C, the critical upper limit for most life.

Walker et al.3 have proposed that the climate could have been controlled solely by abiological negative feedback involving a gradual decline in the atmospheric partial pressure of CO₂ in response to a continuous increase of the Sun's luminosity. Briefly, an increase in temperature accelerates the rate of reaction between CO₂ and calcium silicate rock. The input of CO₂ from tectonic sources is assumed to be constant so that an increased heat flux leads to increased weathering of the rock, a faster removal of CO_2 and hence a lower atmospheric CO_2 partial pressure. This cybernetic process acts to resist the rise in temperature which would otherwise result from the increase in solar luminosity.

This abiological mechanism could have operated early in the Earth's history but the resulting climatic control would have been easily perturbed by fluctuations in the volcanogenic flux of CO₂. These effects could have been exaggerated by the positive feedback loops introduced by the ocean-atmosphere interaction. As the solubility of CO₂ in water decreases with increasing temperature, an atmospheric (and hence oceanic) warming would result in a release of CO₂ to the atmosphere which would produce a further temperature rise. A corresponding positive feedback would occur on cooling. At present geological input and removal constitute only a few tenths of a per cent of the biologically driven fluxes¹⁰ and so it is instructive to see how the biological and geological mechanisms can be

There is little doubt that current weathering of silicate rocks is biologically, not geochemically, determined. The partial

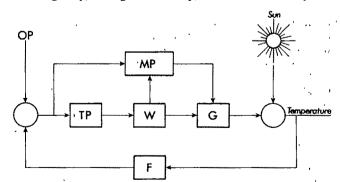

Fig. 1 A feedback process in which the productivity of the terrestrial biosphere (TP) or the marine biosphere (MP) influences the greenhouse effect (G) and hence the global mean temperature via control of the atmospheric partial pressure of carbon dioxide. These biological processes modulate the geological control exerted by the weathering process (W) against a constant input from tectonic sources. The loop is closed by the feedback process (F, see text) which transduces from the mean temperature a productivity that can be compared with the operating productivity (OP) of the biosphere.

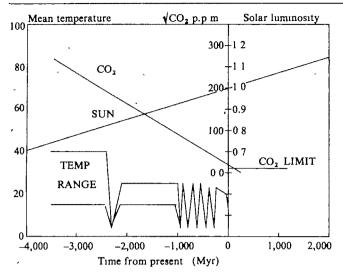

Fig. 2 Evolution of the climate showing the variation of solar luminosity, relative to its present value taken as 1.0. Also illustrated on the same time scale are the proposed decline in carbon dioxide concentration, expressed as the square root of the concentration in parts per million (p.p.m.) by volume and the approximate range of mean surface temperatures in °C (see text).

pressure of CO₂ in the soil where the chemical weathering takes place is 10-40 times higher than the atmospheric level¹¹. These high partial pressures are maintained by the biological oxidation of organic detritus and the rate of oxidation approximately doubles for each 10 °C rise in temperature. The biota seem to act as a sensor of temperature change and as an amplifier to magnify the rate of weathering of the silicate rocks and pumping of CO₂ from the air. The present geochemical balance for CO₂ between input from tectonic sources and removal by weathering¹⁰ requires a partial pressure in the soil of nearly 10 mbar.

The direct involvement of the biota in weathering would only be possible after the evolution of a land microfauna and flora and the establishment of viable soil communities. Although such communities probably predate the invasion of land as deduced from fossils, it is possible that life was largely confined to the sea during the Archaean. Once communities based on photosynthetic carbon fixation were established in the oceans, however, they could amplify indirectly the geochemical feedback. In the contemporary ocean the biota limit the atmospheric partial pressure of CO₂ by maintaining a continuous flux of particulate organic matter into the deep ocean¹². This flux results from primary production in the surface layers which is limited by the rate of supply of nutrients, notably nitrogen and phosphorus, from riverine inputs and from the slow recirculation of nutrient- and carbon dioxide-rich deep-ocean water. If, as suggested by the geological model³, the rate of rock weathering increases due to a rise in global temperature, then the rate of supply of nutrient elements to the oceans will also increase. This will enhance primary productivity and further reduce atmospheric CO2 levels. If, on the other hand, the temperature falls the nutrient supply will diminish, productivity will decrease and excess CO2 will be released from the recirculating deepocean water into the atmosphere, thus encouraging a temperature rise¹². Here, too, the biota can use geologically driven processes to provide additional temperature stabilization. If life ceased now, the new geochemical balance would require an increase of atmospheric CO2 and hence temperature until removal by weathering again equalled the input of CO₂ from volcanoes. The present low atmospheric CO2 pressure and relatively low temperature are therefore a direct consequence of life. This is consistent with the Gaia hypothesis² which suggests that evolutionary pressures ensure that biologically driven processes which influence the chemical composition of the atmosphere and hence the climate so as to keep the environment optimal for the biosphere will have been preferentially selected.

Figure 1 illustrates a highly simplified model of the combined biological and geological regulation of temperature. As the temperature falls, CO_2 fixation by photosynthesis and chemical weathering declines until at $\sim\!0\,^\circ\mathrm{C}$ it nearly ceases. CO_2 input from tectonic sources continues and the atmospheric partial pressure of CO_2 will rise. Through the greenhouse effect, this increase resists any further decline in temperature. In a similar way high temperatures and high CO_2 pressures are both conductive to rapid weathering which serves to resist a continuing rise in temperature. Thus the mean surface temperature will tend to a value optimal for the contemporary biota within the other constraints of its planetary environment.

Figure 2 illustrates the probable solar output from 4,000 Myr ago to 2,000 Myr hence and gives on estimate of the corresponding global mean temperature and CO₂ partial pressure. Solar luminosity is predicted to increase, according to Newkirk¹. An alternative analytical expression for the time variation of solar luminosity¹³ might be useful for more detailed calculations.

The range of past temperatures is not accurately known. That shown in Fig. 2 is our estimate of the probable limits of palaeoclimates and it is based on the following assumptions. (1) During the Archaean the biosphere was wholly prokaryotic. As the upper temperature limit for contemporary prokaryotes is 50 °C, the upper limit for the Earth's mean temperature was set lower, at 40 °C, to allow for zonal and other variations. No glaciations are known during this period 14,15 so the lower limit of temperature is set at 15 °C, close to the present value. (2) -2,200 Myr marks the end of the Archaean and the first extensive glaciation^{14,15}, as well as the appearance of free oxygen. Temperatures might have risen after this glaciation to Archaean levels or they may have been similar to the levels now thought characteristic of the interglacial periods—20-30 °C. We chose the latter estimate as the upper limit from -2.2 Gyr until the present. The lower limit is set by the physical properties of water. There is no indication that total freezing took place, so a mean temperature of 0 °C or below is very unlikely. Glaciations^{14,15} are associated with mean temperatures of 5-10°C and interglacials with lower limits perhaps 5-15 °C higher. The time scale of the figure is so compressed that the present interglacial climate cannot be resolved from the low values of the last glaciation 10,000 yr ago.

The other quantity illustrated in Fig. 2 is the CO_2 pressure needed to compensate for the changing solar luminosity. This estimate is based on a partial pressure 3,500 Myr ago of 7,000 p.p.m. (refs 4, 17). It is linked to the present value of 320 p.p.m. on the assumption of a linear relationship between the square root of the CO_2 pressure and the solar luminosity for a constant mean temperature. The exact relationship may be different, however, and an analysis of the geological mechanism³ suggests that a 2/3 power relationship might be more appropriate. Nonetheless, such differences are unlikely to affect the qualitative conclusions that can be drawn from Fig. 2.

If the principal agent for temperature regulation is the partial pressure of CO2 in the atmosphere and even if the solar luminosity is constant, it seems that we are very close to the lower limit of possible adjustment; also there are no other gases in the air which could serve significantly in this way by the reduction of their partial pressures. Other mechanisms such as an increase in albedo by desert cover might sustain an equable climate but as observed by Henderson-Sellers 16, this is generally neutralized by a concomitant change in cloud cover. On the other hand, if we accept the predicted increase in luminosity and assume that the future decline of CO₂ matches the solar output as may have been the case in the past, then 150 p.p.m. pressure will be reached in about 100 Myr. This concentration is the lower limit tolerable for photosynthesis. Some adaptation to lower CO₂ concentrations and to higher temperatures is possible but it would not buy much time. In human terms the crisis is still infinitely distant but in terms of the life span of the biosphere,

rich with familiar metazoans, we might forecast an end to the long spell of cool and favourable climate.

We thank Dr A. F. Tuck and Professor R. M. Garrels for stimulating suggestions.

LDH-B genotype-specific hatching times of Fundulus heteroclitus embryos

Leonard DiMichele & Dennis A. Powers

Department of Biology, The Johns Hopkins University, Baltimore, Maryland 21218, USA

The evolutionary significance of protein polymorphisms has long been debated. Exponents of the balanced theory advocate that selection operates to maintain polymorphisms, while those of the neoclassical school argue that most genetic variability is selectively neutral1. As the 'neutralist' hypothesis implies that allelic isozymes are functionally equivalent, some investigators have examined the biochemistry of protein polymorphisms² while others have concentrated on life history correlates 16-23. Few studies, however, have established that in vitro functional differences are reflected at the whole organism level^{5,21-23}, yet this is a critical link in understanding the significance of protein polymorphisms. We have studied the effects of the kinetically different lactate dehydrogenase-B (LDH-B) allelic isozymes on the rate of development and physiological performance of the fish, Fundulus heteroclitus, and report here that hatching time is highly correlated with LDH-B genotype: LDH-B'B' individuals hatch before LDH-BbB fish while heterozygote (LDH-BaBb) hatching is intermediate. The basis for this phenomenon may be a differential ability to deliver oxygen to respiring tissues. As precisely timed hatching is critical to the survival of Fundulus²⁴, such differences in hatching time between LDH-B genotypes may be an important component of the species' evolutionary strategy.

The LDH-B polymorphism in F. heteroclitus is due to two co-dominant alleles 25,26 which exhibit a cline in gene frequencies along the Atlantic Coast of the United States^{4,27}. We have shown that there are temperature- and pH-dependent kinetic differences between the LDH-B allelic isozymes⁷. Moreover, intra-erythrocyte ATP differences among individuals are correlated with LDH-B phenotype³. The role of ATP as an allosteric modifier of Fundulus haemoglobin is similar to that of 2,3diphosphoglycerate in human red blood cells, in that it decreases the affinity of haemoglobin for oxygen^{28,29}. Thus, fish with the highest levels of intra-erythrocyte ATP (that is, LDH-Bbb) have the lowest blood oxygen affinity³. As respiratory stress has been shown^{30,31} to trigger the hatching mechanism in Fundulus, we hypothesized that the hatching times of LDH-B genotypes should differ because of differences in blood oxygen affinity. Specifically, LDH-B*B* fish should hatch before LDH- B^bB^b individuals.

As an initial test of this hypothesis, fertilized eggs were obtained by stripping gametes from males and females that were randomly paired. Each of the resulting clutches was incubated in a separate Petri dish at 20 °C, pH 7.0 and 15% salinity (Instant Ocean). The incubation medium was changed daily and the fry were collected as they hatched. The LDH-B genotypes of each parental pair and their offspring were determined by gel electrophoresis 26,27 (see Fig. 1). Clearly, hatching of LDH-BaBa eggs was predominant in the first 3 days, while $LDH-B^bB^b$ eggs predominated in the last 3 days. The overall mean hatching times were 11.9, 12.4 and 12.8 days for the LDH-BaBa, LDH-BaBb and LDH-BbBb genotypes, respectively. Individual crosses in which there were more than one genotype also showed that LDH-BaBa eggs hatched before $LDH-B^aB^b$, which in turn hatched before $LDH-B^bB^b$ (Fig. 1).

In addition to establishing an ordered hatching of LDH-B genotypes, our analysis (Fig. 1) also indicated variations between crosses that were not due to the LDH-B locus. If these variations were due to other loci, then pooling gametes from many individuals before fertilization should dramatically reduce the variation between crosses. To test this hypothesis, we performed experiments in which adult fish were segregated by LDH-B genotype into breeding stocks²⁶. Specific LDH-B crosses were made by pooling gametes before fertilization. Consistent with our expectation, these experiments (Tables 1 and 2) almost eliminated variation between similar crosses. Thus, some of the variation among the 20 random crosses in Fig. 1 must have been due to contributions from other loci. On the other hand, Tables 1 and 2 indicate that there are still highly significant differences (P < 0.01) in hatching time between LDH-B genotypes. These data (Tables 1 and 2), together with

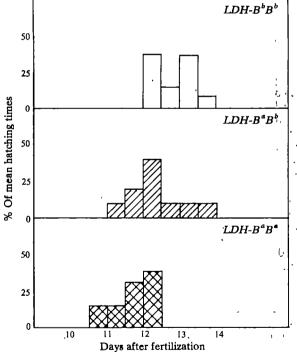

Fig. 1 Distribution of mean hatching times for three LDH-B genotypes from 20 random crosses. Analysis of variance³⁶ indicated significant differences between the crosses (P < 0.05); Duncan's multiple range test³⁶ showed that some of this variation was due to LDH-B genotype (for example, all the LDH-BaBa× $LDHB^aB^a$ crosses hatched before all the $LDH-B^bB^b \times LDH-B^bB^b$ crosses; P < 0.05). There were also significant differences, however, between similar crosses (for example, two of the LDH- $B^aB^a \times LDH$ - B^aB^a crosses hatched sooner than three other crosses of the same type; P < 0.05). The histogram shows the distribution of mean hatching times among genotypes irrespective of parental cross. Separate analyses of each cross in which there were offspring of more than one genotype, showed significant differences (P < 0.05) in hatching time between genotypes in each case.

Replicate	N	LDH-B ^a B ^a	$LDH-B^aB^b$	$LDH-B^bB^b$
1	2,142	12.0	12.8	12.9
2	1,273	11.9	12.0	13.1
3	1,396	12.4	12.8	14.8
4	1,051	12.5	12.5	14.3

Sperm and eggs from 40 LDH-BaB males and 40 LDH-BaB females were pooled in separate dishes and then mixed to make each cross.

N, total number of offspring from each cross.

*The data were analysed by a two-way analysis of variance of unweighted means³⁶, which provides a conservative estimate of the variance between genotypes. The differences between genotypes was found to be significant (P < 0.01); there were also significant differences between replicates (P < 0.05) but this estimate is not conservative because the MS_{error} term had to be calculated separately.

the consistent trend from the 20 random crosses (Fig. 1), demonstrate that hatching in F. heteroclitus occurs generally in the following order: LDH-BB phenotype before LDH-BB, then LDH-BbBb.

The eggs of F. heteroclitus are laid in empty mussel shells³² between the leaves of the marsh grass, Spartina alterniflora²⁴, or in the sand above the mean high tide³³. In these conditions, the eggs incubate in air for most of their developmental period. Hatching occurs when eggs laid at one spring tide are immersed in water by the following spring tide. As water covers the eggs, there is a drop in environmental oxygen at the egg surface which is the hatching cue for the embryo³⁰. Therefore, overall plasticity in hatching times may be important in protecting F. heteroclitus populations that live in variable environmental conditions. Our data suggest that premature hatching cues (for example, rainstorms) would select largely against LDH-BBB individuals, while late hatching (that is, after the tide has retreated) would select primarily against the LDH-Bbb phenotype. This argument is particularly compelling in view of the finding of Meredith and Lotrich³⁴ that the mortality of F. heteroclitus in age-class 0 (eggs to fry of 59 mm) is >99.5%.

As respiratory stress initiates hatching and blood oxygen affinity is correlated with LDH-B genotype via intra-erythrocyte ATP concentrations, the simplest interpretation of our data is that the differences in hatching times result from functional differences between LDH-B allelic isozymes. However, our results do not exclude the possibility that other genes, tightly linked to the LDH-B locus, may be responsible for the observed effects on hatching time. Whatever the molecular basis for these differences may be, it is clear that genetic variability at the LDH-B locus (or a closely linked one) leads to a 'developmental polymorphism'35. Determination of the evolutionary significance of this whole organism phenomenon and its underlying molecular mechanisms should help resolve

Table 2 Mean hatching times (days) for offspring from $LDH-B^aB^a \times$ $LDH-B^aB^a$ and $LDH-B^bB^b \times LDH-B^bB^b$ 'mass' crosses

Local application of retinoic acid

to the limb bond mimics the action of the polarizing region

C. Tickle*, B. Alberts†, L. Wolpert* & J. Lee*

* Department of Biology as Applied to Medicine, The Middlesex Hospital Medical School, London W1P 6DB, UK † Department of Biochemistry, University of California, San Francisco, California 94143, USA

The polarizing region, a small group of cells at the posterior margin of the limb bud, acts as a signalling region to specify the pattern of structures which develop across the antero-posterior axis of the limb¹. When a polarizing region is grafted to the anterior margin of a second limb, a mirror-image symmetrical limb develops^{1,2}. There is indirect evidence that the signal from the polarizing region is a diffusible morphogen³. In an attempt to identify the nature of the putative morphogen, we have developed a method whereby extracts of polarizing region cells and chemicals can be locally applied to the wing bud by being bound to implanted beads and other inert carriers. The chemicals tested included hyaluronidase, dibutyryl cyclic AMP and thalidomide. All experiments have been negative until, at the suggestion of Dr J. Pitts, we tested retinoic acid because of its effects on cell-to cell communication and cell differentiation, and we have now for the first time been able to mimic the action of the polarizing region with a defined chemical.

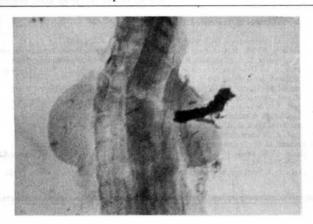

Fig. 1 Dorsal view of part of a fixed embryo to show how the grafts were performed. A strip of retinoic acid-impregnated paper has been placed in an anterior position in the right wing bud.

Small strips of Whatman diethylaminoethyl cellulose (DEAE) paper (~500 µm long and 100 µm wide) were soaked in a range of concentrations of all trans-retinoic acid (Sigma, type XX) dissolved in dimethyl sulphoxide (DMSO; Sigma, grade 1) for 15-30 min. These strips were then grafted wet to slits cut in the anterior margins of wing buds at stages of development before the digits are specified (Hamilton-Hamburger stages 20-21). The slits to which the papers were grafted were cut into the wing at a level opposite somite 16 or the border between somites 16 and 17. Figure 1 shows the type of operation but in this case the paper has been grafted more posteriorly. The embryos were left to develop for a further 6-7 days before they were fixed and the cartilage pattern of the grafted wings examined. The results obtained are presented in Table 1.

DEAE-cellulose papers alone, papers soaked in DMSO (unpublished results of J. McQueen) and papers soaked in the lower concentrations of retinoic acid tested (0.01-2.5 mg ml⁻¹) did not produce additional digits (Fig. 2a). Instead, the most anterior digit, digit 2 and/or the anterior forearm element, the radius, is occasionally absent (digit 2 missing in 2/27 cases, the radius missing in 6/27 cases). However, papers soaked in concentrations of retinoic acid higher than 2.5 mg ml-1 can produce additional digits in the wings of the surviving embryos. We have previously shown that grafts of cells with high polarizing activity lead to the development of a complete duplicate set of digits: 432, in mirror-image symmetry with the normal set, 234, while grafts with progressively lower activities specify a duplicate 3 and 2 and then a duplicate 2 only4.5. The pattern of duplicated digits obtained with retinoic acid suggests that the response to this chemical is similarly dose dependent. With grafts of papers soaked in 5 mg ml⁻¹ retinoic acid, 50% of the wings that develop have duplicate digits and in most cases consist of an additional digit 2 only (Fig. 2b), while with grafts of papers soaked in 7.5 mg ml⁻¹ retinoic acid, nearly every wing that develops has additional digits and furthermore, half of these have duplicated both digits 4 and 3 (Fig. 2c). Duplications were also obtained at concentrations of 10 mg ml⁻¹ using pure retinoic acid (Hoffmann-La Roche). Although the pattern of the production of additional digits mimics the action of the polarizing region, the detailed patterns of cartilage in the duplicated wings, in some cases, at the higher concentrations of retinoic acid resemble those typically produced when signalling is unimpaired but growth is reduced⁶.

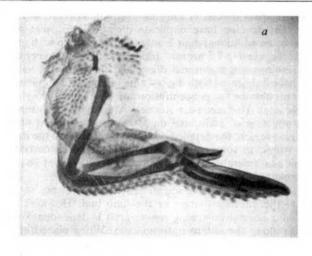

Our assay for polarizing region activity involves placing the graft at the anterior margin of the limb bud. However, the effect of a normal polarizing region graft is dependent on its position along the antero-posterior axis. When placed at the posterior margin it has no effect. We therefore grafted retinoic acid-impregnated papers (10 mg ml⁻¹) to the posterior margin of nine wing buds. Seven gave normal wings, one lacked digits and another gave a tiny extra sliver of cartilage anteriorly. These results are consistent with local application mimicking the polarizing region rather than a systemic effect. Note that the survival of the embryos receiving grafts of the papers soaked in the high concentrations of retinoic acid that lead to the production of additional digits can be reduced (Table 1). Indeed, using two batches of retinoic acid, scarcely any embryos survived that received grafts of papers soaked in retinoic acid at 10 mg ml-1, while with a third batch 100% of the treated embryos survived. Associated with the production of additional digits, embryos that had received grafts of retinoic acid-impregnated paper to the limb bud also showed beak deformities. The beak deformities, which will be described more fully elsewhere, affected the upper beak only and ranged from a complete absence of the upper beak to a slight shortening.

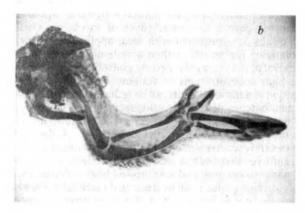

Retinoic acid and vitamin A have a wide variety of effects on cells, for example, inducing differentiation⁷, blocking gap junctions⁸ and affecting glycoprotein synthesis⁹. Added systemically, retinoic acid also has teratological effects on limbs, such as damaging cartilaginous elements¹⁰. It probably acts through a retinoic acid binding protein in the cytoplasm⁹.

Further work is required to determine whether retinoic acid is itself a morphogen or is converted in the limb to such a morphogen; alternatively, it may activate some other system or simply be acting as a weak acid. Moreover, a cautionary note is struck by the fact that the concentration of retinoic acid required to produce extra digits can approach that lethal to the embryo. However, cells soaked in several other toxic chemicals never produced extra digits when grafted to anterior positions in early buds¹¹. These results with retinoic acid also contrast with those studies on neutral induction, where substances producing 'sub-cytolytic' changes trigger neural differentiation without a change in pattern¹². Here, we have the first example

Table 1 The digit pattern in wings that developed following grafts of paper soaked in retinoic acid solutions to anterior positions in early wing buds

					Dig	it pattern		
Concentration of retinoic acid solutions in which papers were soaked (mg ml ⁻¹)	No. of grafts	No. of survivors	Normal 234	2234	3 3 4 or 3 2 3 4	4 3 3 4 or 4 3 4	43234	Other
0 (controls)	6	5	4	4	-	-	-	One 3 4

Long-term complications of virus-induced diabetes mellitus in mice

Ji-Won Yoon, Merlyn M. Rodrigues*, Carol Currier* & Abner Louis Notkins

Laboratory of Oral Medicine, National Institute of Dental Research and * Clinical Branch, National Eye Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

In man, the early metabolic abnormalities associated with diabetes mellitus are followed by various long-term complications1. The cause of these complications is not clear, but they may be secondary to persistent abnormalities in blood glucose levels². In mice, several viruses can infect and destroy pancreatic β cells and produce acute-onset insulin-dependent diabetes mellitus (IDDM) characterized by hypoinsulinaemia, hyperglycaemia, glycosuria, polydypsia and polyphagia3. The virus most studied is the M variant of encephalomyocarditis (EMC) virus4.5. Long-term complications, however, have been difficult to demonstrate because in most mice, the diabetes is transient and mild. Recently, by plaque purification, we have shown that the M variant of EMC virus actually has two stable variants: one diabetogenic (designated D) and the other nondiabetogenic (designated B). Further studies revealed that the B variant reduces the severity of the diabetes produced by the D variant6. We now report that when mice are inoculated with the D variant alone, many develop severe and prolonged hyperglycaemia followed by some of the long-term complications of diabetes, including reduced lifespan, glomerulosclerosis and ocular changes.

SJL/J male mice, 5-6 weeks old, were infected with 5×10^5 plaque-forming units (PFU) of the D variant of EMC virus and at various intervals over 6 months, non-fasting blood glucose levels were determined and mortality calculated. As seen in Table 1, 7 days after infection, 85% of the mice were diabetic with a mean blood glucose level of 426 ± 94 mg %. The number of diabetic mice decreased with time and at 150 days, only 12 of the mice were still diabetic with a mean glucose level of 290 ± 44 mg %. In contrast, age-matched uninfected controls showed no elevation of blood glucose levels. The EMC-infected diabetic animals also showed substantially higher mortality than age-matched uninfected controls or infected but non-diabetic mice (Table 1). Between 7 and 30 days after infection, only 7.1% of the diabetic mice died. At each interval thereafter, there was an increase in mortality associated with the duration of diabetes. In contrast, the infected non-diabetic mice, including those that converted from the diabetic to the non-diabetic state, showed low mortality. After 6 months, the cumulative mortality of the infected diabetic mice and uninfected controls was 64% and 17% respectively.

Evidence that the elevated blood glucose levels were responsible for the increased mortality is provided by the fact that, at each of the intervals up to 120 days, the overall mortality of the diabetic mice having blood glucose levels above the median was about three times greater than that of those having blood glucose levels below the median.

In addition to the increased mortality, the diabetic mice showed evidence of long-term complications. At 2 months after infection, light microscopy revealed little or no change in the kidney, but after 4 months, mild to moderate mesangial thickening was found. At 6 months, the changes were quite dramatic: all 12 diabetic mice that were killed at 6 months revealed thickening of the Bowman's capsule, prominent nodular and diffuse glomerulosclerosis (Fig. 1b), an increase in the mesangial matrix and thickening of the tubular and peripheral glomerular basement membranes. Occasional glomeruli had capsular drop lesions, and the afferent and efferent arterioles showed evidence of hyaline sclerosis. In contrast, the glomeruli, tubules and arterioles of 12 age-matched uninfected controls (Fig. 1a) and 3 age-matched infected but non-diabetic mice appeared essentially normal.

Transmission electron microscopy of kidneys from diabetic mice revealed moderate thickening of the peripheral glomerular basement membrane. Approximately 20 glomeruli from each of 12 control and 12 diabetic mice (at 6 months) were examined and 5-20 measurements were made per sample as described previously⁷. The peripheral glomerular basement membrane was 91 ± 3.1 nm thick in uninfected controls (Fig. 1c) and 382 ±

6.2 nm in mice that were diabetic for 6 months (Fig. 1d). The foot processes were fused in some areas but intact in others, and the mesangium was thickened markedly. Uninfected agematched controls showed normal glomerular structure, normal basement membrane and distinct delineation of the glomerular foot processes.

Approximately 10 glomeruli from each of 12 control and 12 diabetic mice (at 6 months) were examined also by scanning electron microscopy. The glomeruli of uninfected mice revealed the normal contour of Bowman's capsule, epithelial cells and foot processes (Fig. 1e), but in diabetic mice, there was effacement of the surface contours (Fig. 1f) and considerable atrophy of the glomeruli, which in some cases occupied only one-third of the Bowman's capsule.

In addition, long-term ocular abnormalities were observed in the same 12 diabetic mice that were examined for kidney lesions. The corneal epithelium of mice that were diabetic for 6 months showed marked irregularity of all layers (Fig. 2b) compared with age-matched uninfected controls (Fig. 2a). In particular, the basal layer and the junctional complexes were focally deficient. The stroma and Descemet's membrane were normal. We prepared retinal capillaries from 6-12 diabetic and control mice by trypsin digestion⁸ and examined them by light and scanning electron microscopy. Capillaries from mice that were diabetic for 6 months revealed a moderate decrease (~50%) in the number of pericytes with the loss of the usual

Fig. 1 Kidney sections from uninfected controls and EMC-infected mice that were diabetic for 6 months. Light microscopy of a, control mouse showing normal glomeruli, tubules and Bowman's capsule (double arrows); diabetic mouse (6 months duration) showing prominent nodular glomerulosclerosis (long arrows) and thickening of Bowman's capsule (double arrows) (periodic acid-Schiff, ×145). Transmission electron micrographs of kidney from a diabetic mouse (d) showing marked thickening of the peripheral glomerular capillary basement membrane (I-I) compared with an uninfected control (c) (×15,750). Scanning electron micrograph of kidney from diabetic mouse showing f, focal effacement of the normal glomerular epithelial cells with loss of foot processes (arrow), compared with e, the usual surface pattern of epithelial cells having abundant arborizing foot processes (double arrow) normal kidney (×3,700). Sections were prepared by standard methods and examined using a Phillips 400 electron microscope or a JEOL SM 35 scanning electron microscope.

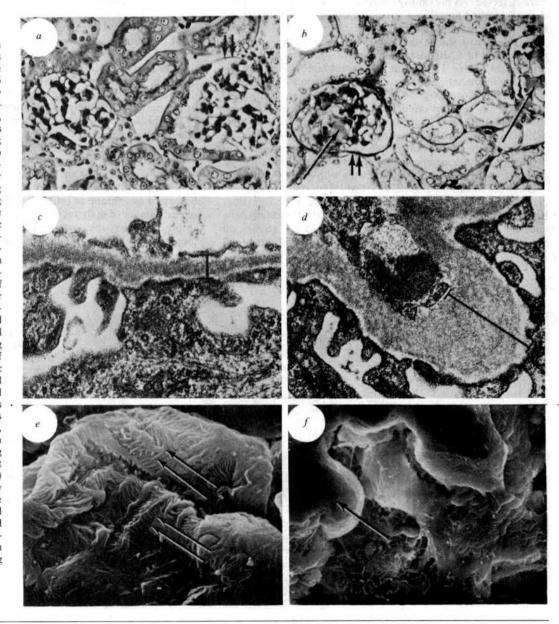

Table 1 Blood glucose levels and mortality of EMC-infected diabetic and non-diabetic mice

Days after infection	No. of animals at start of each period	Infected								
		Diabetic			Non-diabetic			Uninfected controls		
		Glucose	Deaths/ diabetics	Mortality (%)	Glucose	Deaths/ diabetics	Mortality (%)	Glucose	Deaths/ controls	Mortality (%)
7-30	100	426 ± 94	6/85	7.1	174 ± 29	0/15	0	156 ± 5	0/89	0
30-60	94	401 ± 92	16/78	20.5	166 ± 19	0/16	0	152 ± 14	1/89	1.1
60-90	79	367 ± 81	10/61	16.4	163 ± 13	0/18	0	152 ± 11	4/88	4.6
90-120	68	332 ± 77	16/43	37.2	159 ± 14	0/25	0	154 ± 12	5/85	5.9
120-150	52	306 ± 70	9/21	42.9	167 ± 20	0/31	0	159 ± 16	2/80	2.5
150-180	43	290 ± 44	7/12	58.3	168 ± 23	1/31	3.2	162 ± 19	3/78	3.9

A mouse was scored as diabetic if the non-fasting glucose level was ≥ 3 s.d. above the mean of uninfected controls. The glucose concentrations shown are the mean \pm s.d. at the beginning of each period; those shown for the infected non-diabetic animals are < 3 s.d. above the mean of uninfected mice. Fourth column, number of deaths at end of each period divided by number of diabetic mice at beginning of each period. Column 7, number of deaths at end of each period divided by number of non-diabetic mice at beginning of each period. Column 10, number of deaths at end of each period divided by number of uninfected controls at beginning of each period.

1:1 ratio of pericytes to endothelial cells (Fig. 2c,d). In $\sim 60\%$ of the diabetic mice, the retinal capillaries showed a minimal to moderate (twofold) increase in the thickness of the basement membranes. Microaneurysms were not detected in any of the animals by the PAS-trypsin digestion method^{8,9} and no cataracts were detected. As previously observed¹⁰, the pancreatic tissues showed marked atrophy of β cells in the islets of Langerhans and preservation of acinar tissue.

Thus we have shown that the decrease in the mean blood glucose level of EMC-infected mice over the 6 months of the experiment (Table 1) was due to several factors. First, many of the highly diabetic mice died, leaving survivors having much lower blood glucose levels. Second, monthly monitoring of individual animals revealed that the blood glucose of these animals also decreased with time (data not shown). Moreover, $\sim 20\%$ of the originally diabetic animals converted to the non-diabetic state by 150 days after infection. Whether regeneration of β cells or other compensatory factors is responsible for the decrease in the severity of the diabetes with time is unknown.

Using the M variant of EMC virus, which produces less severe diabetes, and by examining mice 4 months after infection, Kanich et al.¹¹ observed some mesangial thickening in diabetic mice by transmission electron microscopy. In our studies on the D variant of EMC virus, not only did we find mesangial

thickening, but also an increase in the thickness of the peripheral glomerular basement membrane and Bowman's capsule. In addition, we found prominent nodular and diffuse glomerul-sclerosis, as well as afferent and efferent arteriosclerosis. These changes are compatible with the renal complications seen in human diabetes mellitus, especially of the Kimmelstiel-Wilson type¹². The most striking similarity to human diabetic nephropathy was the change in the peripheral glomerular basement membrane, which was thickened by as much as fourfold compared with control mice. Such changes have not been well documented in alloxan-induced or streptozotocin-induced diabetes, which generally have been associated with varying degrees of mesangial thickening without significant thickening of the peripheral gomerular basement membranes^{9,13}.

The histopathological changes seen in the cornea of our diabetic mice were not dissimilar to those which predispose to corneal erosion in human diabetes¹⁴. Moreover, the decrease in the number of pericytes in the retinal vessels of diabetic animals, with the loss of the usual 1:1 ratio of pericytes to endothelial cells and the moderate increase in thickness of the basement membrane of retinal capillaries, is also characteristic of early stages of diabetes in man¹⁵. These changes are thought to precede microaneurysms. Microaneurysms usually occur in long-term diabetes in humans and in diabetic animals such as

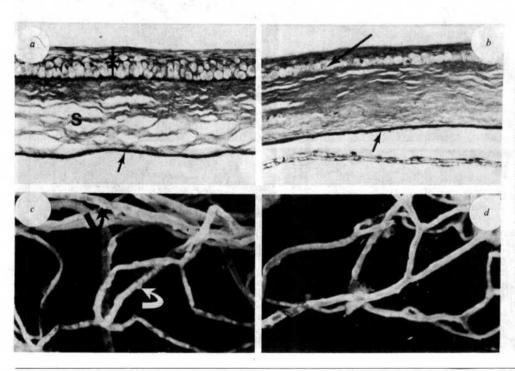

Fig. 2 The corneal epithelium of uninfected mice (a) show the usual stratification (cross) and glycogen content (periodic acid-Schiff; ×236). Cornea from mice that were diabetic for 6 months (b) show irregular stratification and moderate oedema of the epithelium, particularly of the basal layer (long arrow) (periodic acid-Schiff; ×230). The stroma (S) and Descemet's membrane (short arrow) are normal. c, Scanning electron micrograph of retinal capillaries obtained by trypsin digestion from uninfected mice, showing the normal pericyte distribution (arrows). d, A moderate decrease in the number of pericytes is observed in the trypsin digest of retinal capillaries from mice that were diabetic for 6 months $(\times 308).$

the monkey and dog, but have not been demonstrated convincingly in small animals such as the mouse and rat8. The possibility that microaneurysms may develop in EMC-infected mice that are diabetic for >6 months is now being investigated.

In conclusion, our studies in mice show that infection with the D variant of EMC virus produces both the acute and at least some of the long-term complications of IDDM.

Neural regulation of muscarinic receptors in chick expansor secundariorum muscle

R. A. Rush, M. F. Crouch, C. P. Morris & B. J. Gannon

Centre for Neuroscience and Departments of Human Physiology and Human Morphology, The Flinders University of South Australia, Bedford Park, South Australia 5042, Australia

We have recently observed the loss of muscarinic receptors from a smooth muscle of the chicken wing, the expansor secundariorum, during post-hatch development¹. The nerve supplying the muscle has been shown to consist mainly of sympathetic fibres that, when stimulated, cause muscle contraction by the release of noradrenaline and subsequent activation of α adrenoreceptors. Although no acetylcholine release has been detected in isolated nerve-muscle preparations2, the presence of a cholinergic input has not been clearly excluded. Kuromi and Hagihara2 observed that atropine was ineffective in blocking the nerve stimulation-induced contraction of the muscle, whereas phentolamine partly and guanethedine totally abolished the contraction. We have now examined the effect of denervation of the muscle 1 day after hatch on the binding of ³H-quinuclidinyl benzilate (³H-QNB), a radioligand for mus-carinic receptors^{3,4}. Our results indicate that the normal loss of muscarinic receptors from the expansor secundariorum is prevented by denervation. This observation is important as it demonstrates the regulation of a receptor population by a nerve supply that apparently does not release the corresponding transmitter.

Muscles from 1-day old birds bound 0.165±0.024 fmol of ³H-QNB per mg wet weight. In 3-week old chicks that were unilaterally denervated at 1 day old, no significant loss of binding sites occurred (0.140 ± 0.018 fmol per mg wet weight, P>0.1), whereas binding in the contralateral, innervated muscle was significantly lower (0.093 ± 0.013, fmol per mg wet weight, P < 0.001). An anomalous, small difference in the binding was detected between the contralateral, innervated muscle and muscle from normal, unoperated birds (Fig. 1).
